RAISING LIFE

NOTHING IS MORE PRECIOUS THAN LIFE, AND THAT'S THE PHILOSOPHY THAT DRIVES PHILEO.

As global population continues to increase, the world faces a growing demand for food and greater sustainability challenges.

Working at the crossroads of nutrition and health, we are committed to delivering future evidence-based solutions that enhance ruminant health and performance.

In each and every country, our team's progress is led by the most advanced scientific outcomes as well as the field input of experienced farmers.

Science For A Better Life

A 3D molecular model of a protein structure, rendered in a teal color, is highlighted within a white circular frame. The background features a light blue gradient with faint, semi-transparent DNA double helix structures.

Driving innovation in animal health

Exploring the potential of innate immunity

At Bayer, our mission is Science For A Better Life, and we are committed to offer innovative solutions to change the way veterinarians and farmers approach infectious diseases in livestock. That is why we are actively engaged in exploring the potential of innate immunity in animal health. Visit us on www.innateimmunity.bayer.com

A new way to
address immune
suppression and
protect her potential

Even your best dairy farmers need a little help protecting their herds

Introducing **Imrestor™** (pegbovigrastim injection), a brand new, innovative immune restorative for periparturient dairy cows and heifers. During the critical time around calving when a dairy cow's immune system is suppressed, Imrestor helps restore the function and increase the number of bacteria-fighting neutrophils. It's the helping hand your dairy producers need.

**To ensure your farmers are protecting the potential of their herds,
contact your Elanco representative.**

Bayer: Science For A Better Life

Bayer is a global enterprise with core competencies in the Life Science fields of healthcare and agriculture. Its products and services are designed to benefit people and improve their quality of life. At the same time, the Group aims to create value through innovation, growth and high earning power. Bayer is committed to the principles of sustainable development and to its social and ethical responsibilities as a corporate citizen. In fiscal 2015, the Group employed around 117,000 people and had sales of EUR 46.3 billion. Capital expenditures amounted to EUR 2.6 billion, R&D expenses to EUR 4.3 billion. These figures include those for the high-tech polymers business, which was floated on the stock market as an independent company named Covestro on October 6, 2015. For more information, go to www.bayer.com.

Boehringer Ingelheim

Boehringer Ingelheim Animal Health is committed to providing leading solutions to prevent, treat and cure animal diseases. Every year, we invest more than 10 percent of our net sales in Animal Health to do research at the highest level. At Boehringer Ingelheim Animal Health, more than 3,500 employees worldwide work on the research and development of new medicines and procedures to keep our animal patients healthy. We are driven by the wish to improve animal welfare as an integral part of a healthy future for mankind.

**The Reference
in Prevention
for Animal Health**

HIPRA

HIPRA is a veterinary pharmaceutical company dedicated to the research, production and marketing of products for Animal Health. At HIPRA we are convinced that the future lies in prevention. We are specialists in developing innovative preventive solutions that make it possible to identify existing threats on any livestock farm before they occur, in such a way that we can act to prevent them or minimize their effects. We have a broad range of highly innovative Biological products, an advanced diagnostic service and our own line of Diagnostic kits. We are located in more than 20 countries with our own commercial subsidiaries and production plants strategically situated in Europe and America. Likewise, our large global distribution network enables our products to reach customers in more than 100 countries on all five continents. At HIPRA we maintain a commitment to excellence, to service to livestock farms, to our people and to social, economic and environmental improvement.

MSD
Animal Health

MSD Animal Health

Through its commitment to the Science of Healthier Animals™, MSD Animal Health offers veterinarians, farmers, pet owners and governments one of the widest range of veterinary pharmaceuticals, vaccines and health management solutions and services. MSD Animal Health is dedicated to preserving and improving the health, well-being and performance of animals. It invests extensively in dynamic and comprehensive R&D resources and a modern, global supply chain. MSD Animal Health is present in more than 50 countries, while its products are available in some 150 markets. For more information, visit www.msd-animal-health.com or connect with us on LinkedIn.

MAJOR PLUS PARTNERS

Elanco Animal Health

In Dairy, Elanco is committed to help veterinarians and dairy farmers with innovative solutions to improve cow's health and wellbeing with a focus on The Vital 90™ Days period, a time of great risk and vulnerability for every cow. Health is essential for a sustainable dairy production and herd health status is a key parameter to ensure productivity, efficiency and profitability of dairy farms. So there's nothing more frustrating than watching cows suffer from preventable disease. Elanco can provide tools & solutions to better manage Negative Energy Balance & Immune Suppression during The Vital 90™ Day.

Merial

Merial is a world-leading, innovation-driven animal health company, providing a comprehensive range of products to enhance the health, well-being and performance of a wide range of animals. Merial employs around 6,200 people and operates in more than 150 countries. Merial is a Sanofi company.

Merial is a leader in vaccine technology, a pioneer in parasite treatment for animals and has a solid track record of best-in-class products. Its expertise is extensive in both veterinary pharmaceutical products and vaccines (biological) for companion and production animals.

In the ruminant business Merial is well known for its broad line of products, including: EPRINEX®, IVOMECC®, ZACTRAN®, KETOFEN® and LONGRANGE™.

MAJOR PARTNERS

Ceva

Ceva Santé Animale was the fastest growing Top 10 veterinary health company over the last years. Our expertise centres on the two fields of pharmacy and biology aim to meet the specific demands of the cattle sector. We continually strive to find better solutions to existing and emerging diseases which will in turn improve animal health and productivity. Ceva goes "beyond animal health" to help make cattle production efficient, sustainable and economical.

Zoetis

Zoetis is a global animal health company dedicated to supporting customers and their businesses in ever better ways. Building on 60 years of experience, we deliver quality medicines and vaccines, complemented by diagnostic products and genetic tests and supported by a range of services. We are working every day to better understand and address the real-world challenges faced by those who raise and care for animals in ways they find truly relevant.

SPONSOR PARTNERS

Norbrook Laboratories Ltd.

Norbrook Laboratories Ltd. is a leading veterinary pharmaceutical company, established nearly 50 years ago in Northern Ireland. Norbrook has always worked closely with the agricultural industry to enhance animal health and productivity. Today, it is a global leader in the development of revolutionary veterinary and animal health medicines.

BUIATRICS
CONGRESS**

THANK YOU

EXHIBITORS

Animal Health Ireland

Animal Health Ireland is a not-for-profit, public-private partnership, tasked with controlling livestock diseases not subject to international regulation, with the objective of improving the profitability and sustainability of Irish farmers and the agri-food sector.

Animax

Animax is a pioneering British company specialising in the research, development and manufacture of animal health products. In addition to our well-known Tracesure® range of leaching boluses, other leading brands are Copasure®, Copinox® and Easycal® as well as a whole range of other popular and well respected animal health products.

BCF Technology

BCF Technology have over 30 years' experience manufacturing veterinary ultrasound and distributing world leading on farm ultrasound. Our world leading product range is well known for its high quality imaging, portability, durability and simplicity.

Bimeda Animal Health

Bimeda are a global manufacturer, marketer & distributor of veterinary pharmaceuticals and animal health products. Bimeda is committed to providing quality disease-control solutions, at a market conscious price level.

Bio-X Diagnostics

Bio-X Diagnostics, ISO 9001:2008 certified is developing diagnostic reagents for diseases affecting production animals such as cattle, pigs, horses, small ruminants, trouts and carps. Thanks to the multi-pathogen tests that Bio-X Diagnostics has developed, a single sample can be tested for several pathogens at once.

Biomed Diagnostics

Biomed Diagnostics manufactures the Gold Standard InPouch TF Bovine, a test critical to diagnosis of Trichomoniasis among other diseases. The In Pouch format saves time, improves workflow and reduces sample contamination.

Bovicom

Bovicom, founded 3 years ago, is an IT-enabler for agricultural businesses. With MmmooOgle, Bovicom has created a platform to leverage the power of Big Data in the dairy industry.

Context Publications

From Mastitis, Udder Care, Dairy Herd Health & Management to Animal Nutrition Context Publishes a range of Easy to Use, Colourful Guides ideal for the Vet, Adviser and Professional Farmer. Our online bookshop provides a safe and secure purchasing option.

DairyMaster

DairyMaster is one of the world's leading hi-tech dairy farm equipment manufacturers. Its innovative product range encompasses five key areas: Milking Equipment; Automated Feeding Systems; Manure Scrapers; Cow Health & Fertility Monitors & Milk Cooling Tanks. Technology and innovation is a big focus throughout.

**WORLD
BUIATRICS
CONGRESS**

THANK YOU

EXHIBITORS

Draminski S.A.

DRAMINSKI S.A. company produces specialized equipment for livestock and dairy industry, agriculture and veterinary medicine since 1987. DRAMINSKI is well known all over the world as a producer of small and mobile ultrasound scanners, devices for breeders such as pregnancy, estrus and sub-clinical Mastitis detectors and precision moisture meters.

ECBHM

ECBHM aims at advancing health oriented bovine production management and increase the competency of veterinarians to become a specialist in the speciality of bovine health management.

ECM Echo Control Medicine

ULTRA PORTABLE – HIGHLY EFFICIENT ULTRASOUND SCANNERS Pioneer in the ultra-portable scanners, the French manufacturer ECM proposes portable ultrasounds for field use: IMAGO – IMAGO.S and EXAGO models for Bovine and Small ruminants (pregnancy control, reproduction diagnosis, OPU technique...) ECM also provides technical training, fast after sales service & maintenance.

FarmLab Diagnostics

FarmLab Diagnostics provide diagnostic testing for large animal veterinary practitioners. They offer ISO17025 accredited testing for a range of diseases and develop molecular based tests for custom applications.

Farm Vet

New mobile technology bringing information from farm, practice and external sources into automated animal records. Equips vets to gather data on farm, providing a cutting edge service to modern farmers.

Fera

RAFT and Fera Science Ltd announce their new Environmental Assessment service for product registrations and market extension. Their stand will also support the Centre of Innovation Excellence in Livestock, CIEL.

GD Animal Health

GD Animal Health supports farm managers and their veterinarians, industrial customers and governments, with laboratory diagnostic services, animal health programmes, contract research, research and development, training in our GD Academy and consultancy.

Huvepharma

Huvepharma® is a fast growing global pharmaceutical company based in Europe. With 60 years specialist manufacturing experience in the veterinary Market, ensuring quality, efficacy and choice to both the veterinary surgeon and farmer.

Test With Confidence™

IDEXX

Livestock and poultry producers, laboratories, veterinarians and dairy processors depend on IDEXX diagnostic technologies to make confident decisions about animal health, disease management and reproductive efficiency, and to ensure consumers have access to safe, healthy food and milk. Reproducibility, reliability and accuracy are three of the reasons why more than 1 billion IDEXX tests—including dairy residue tests and milk-based diagnostics—have been run worldwide since 1985.

**WORLD
BUIATRICS
CONGRESS**

THANK YOU

EXHIBITORS

IDvet

Established in 2004 and located near Montpellier, France, IDvet develops, manufactures and markets innovative diagnostic kits for the detection of infectious diseases in farm animals. Our high-quality tests are extensively validated, meet international standards and show innovation through simplified protocols, ready-to-use reagents, and improved test performance.

Intracare

Intracare is a dynamic company that develops sustainable solutions for the agriculture sector by reducing the amount of pathogens (disinfection), improving animal health (feed program), and developing non-antibiotic medicine.

Kyoto Biken Laboratories Inc.

Kyoto Biken Laboratories, Inc. has been developing, manufacturing and supplying vaccines for livestock and companion animals in Japan since 1948. Our mission is to improve animal health and food safety.

Laboklin GmbH

Since 1989, LABOKLIN has become one of the most successful and specialised veterinary laboratories in Europe and offers specialists' expertise in haematology, pathology, microbiology and molecular biology.

Lane Manufacturing Inc.

Lane Manufacturing has been setting the standard in manufacturing reproductive equipment since 1972. Because Lane products are gentle and less stressful to the animal, they yield better, more effective results.

MAI Animal Health

MAI Animal Health™ is THE SOURCE for solutions in animal healthcare. We manufacture and supply innovative, practical products for veterinarians in categories including: Containers, Reproduction, Dental, Specialty, Nutritional and Instruments.

Mervue Laboratories

Mervue Laboratories Ireland is the privately owned nutraceutical division of Inform Nutrition established in 1986. Manufacturing nutraceuticals for Cows, Calves, Sheep, Pigs, Poultry, Horses, Camels and Pets for over 30 years.

Moocall Ltd

Moocall Ltd makes and sells Moocall, a tail mounted calving sensor that sends the farmer a text message about an hour before calving begins. Moocall is a 100% Irish company.

Multimin®

Multimin® is a fast acting-injectable for cattle, containing copper, zinc, manganese and selenium needed for an effective antioxidant system. Multimin® is critical before breeding, calving and at times of stress, to optimize health, immunity & reproduction.

Nimrod

Nimrod Veterinary Products manufactures the Selekt™ system for oral rehydration and clinical nutrition of adult cattle, sheep and goats. The foundation of the system is the high-quality Selekt pump-drencher.

Nimrod Veterinary Products Ltd

**WORLD
BUIATRICS

THANK YOU

EXHIBITORS

Phileo

Nothing is more precious than life, and that's the philosophy that drives Phileo. Backed by 30 years of experience and a global staff of more than 120 people, Phileo designs, develops and delivers innovative solutions to enhance animal health and performance.

Provita Animal Health

Provita Animal Health research, manufacture and market natural animal health products. Leading products from the company include Advance+ a unique silage inoculant, the Hoofsure range for controlling lameness, Protect the only probiotic licenced as a medicine, ProVitaMin the high spec concentrated mineral drench, plus many other innovative products.

Quidee

Cow and calf side testing experts. Smart ideas for smart vets and farmers. Always the newest ideas for your cattle business.

SmaXtec

The Austrian high tech company smaXtec provides customers with a unique herd management tool that enables them to easily manage feeding, reproduction and animal health in real time.

Thermo Fisher Scientific

Thermo Fisher Scientific is the world leader in serving science. Through our Applied Biosystems brand, we deliver veterinary diagnostic tools and services to help address some of the most economically important bovine diseases. This includes a combination of qPCR and ELISA diagnostic kits, universal sample prep solutions and dedicated master mixes.

Vetericyn

Vetericyn® products are the next generation in Animal health care. Vetericyn® products are cost effective and safe for all life stages which makes caring for your livestock that much easier.

Vetoquinol

The 9th largest veterinary pharmaceutical company in the world, Vetoquinol is first and foremost an independent, family-owned company dedicated exclusively to Animal Health. Vetoquinol is recognized for its World-class expertise in anti-infective drugs, control of pain and inflammation and reproduction, providing veterinarians and producers worldwide with high-quality products and adapted services, and striving every day to Achieve More Together.

Focused on efficiency, productivity and disease prevention in cattle

Merial, a trusted partner for the farming industry. By 2050, 70% more food will be needed to feed the world's population. But the planet's not getting any bigger. The meat and milk industries need efficient, sustainable ways to protect their animals' health and increase productivity to keep up with growing global demands. Merial is committed to developing innovative solutions to meet our customers' expectations and to ensure sustainable productivity in their operations. Learn more at [Merial.com](https://www.merial.com).

Evolution of Bovine Surgery

David E Anderson, DVM, MS, Diplomate ACVS
Professor and Head, Large Animal Clinical Sciences

College of Veterinary Medicine, University of Tennessee, Knoxville,
Tennessee, USA

Tremendous advances have taken place in food animal practice, especially in the area of production medicine. However, anesthesia, analgesia, and surgery are still routinely performed on food animals and are primarily performed in the field on farms, ranches, and feedlots. The ability to diagnose and manage surgical problems is one basis for gaining the trust and confidence of a client. These procedures range from castration to laparotomy. Economic, welfare and other constraints often prevent cattle from being referred to surgical centers for specialized care. Difficult surgery can be performed on the farm and advances in surgical materials for the bovine patient make these procedures more approachable. Advancements in bovine surgery, such as minimally invasive surgery, have allowed improvements in bovine surgical care to advance despite economic limitations that are often present. Surgical management of disorders of ruminants continues to evolve with time. Improvements in chemical restraint, surgical technique, and pain management require the ruminant surgeon to remain vigilant in their professional development so that the client and patient can be afforded the best care possible. Constraints experienced by the ruminant surgeon often involve economics, regulatory prohibitions, and dogma. Limitations of ruminant surgery occur because of patient size, weight and mentation; surgeon knowledge, training or skills; and because the client may lack the ability to fully comply with needs during the convalescent period. Dogma, knowledge, skills, and training all can be changed through continuing education, research, and innovation. It has been my life-long desire to enable ruminant surgeons to advance their knowledge of the science and that this will result in personal development in the art of surgical practice. Surgical correction of problems nearly always requires anesthesia and advancements in the clinical practice of surgery often follow improvements in anesthesia. A critical component of peri-operative management of surgical patients includes pain management. Recent advances in analgesic therapy have centered around pain management. I endorse alleviation of pain whenever possible. Recent introduction of analgesic protocols allow for these procedures to be done in many situations and may prevent the loss of valued livestock. Regulatory issues regarding the potential for drug residue adulteration of food products must be heeded to ensure that we do not compromise the client or the consumer.

Pain Management

Management of pain continues to be an important consideration in livestock on which surgical procedures are performed.^{1, 2} In these animals, a balance must be achieved between the need to mitigate discomfort and the economic constraints of the production enterprise. Moral and ethical dilemmas have increased amongst consumers and these concerns have stimulated interest to re-examine the methods used to achieve the shared goals of humane production of safe, affordable animal products for human consumption. Administration of drugs to mitigate pain is variable among veterinarians. In field settings, surgical procedures are performed both on an elective and emergency basis. These surgeries are expected to cause variable degrees of pain or distress. Pain and the biological responses to it are part of a highly integrated multidimensional system that cause animals to react to protect themselves from the noxious stimulus.³⁻⁵ The magnitude of surgical pain is influenced by the procedure, the methods used, and the experience and skill of the practitioner.^{1, 2, 6} Some strategies to inhibit or minimize pain before it occurs (e.g. pre-emptive) are obvious: local anesthesia, general anesthesia, sedation, and tranquilization. Pre-emptive therapy should be done with the intention of controlling pain throughout the

stimulus which may last for hours, days, or weeks. A variety of anti-inflammatory drugs are available for clinical use (Table 1).^{1,2,6} Steroids and non-steroidal anti-inflammatory drugs may have benefits to the patient such as mitigation of pain, lessening of swelling, diminishing inflammation at the incision site and/or damaged tissues, and more rapid patient recovery after the procedure. Non-steroidal Anti-inflammatory Drugs (NSAID's) inhibit cyclooxygenase enzymes (COX).^{1, 2, 6} COX acts on arachadonic acids to liberate prostaglandins and other mediators of inflammation. Multiple isoforms of COX enzyme exist with COX-1 recognized as primarily involved with normal homeostatic mechanisms and COX-2 as an induced enzyme in response to injury. COX inhibitors prevent production of these factors. Non-specific COX inhibitors include aspirin, flunixin, and phenylbutazone. More selective COX-2 inhibitors are rapidly evolving and include etodolac, carprofen, and meloxicam. NSAIDs have differential activity because of the presence of variable receptors and variable drug effects. Our clinical experience suggests that although these drugs may be safer for long-term use (e.g. COX-2 inhibition is less likely to interfere with homeostasis of abomasal mucosa or renal perfusion), COX-2 inhibitors provide less potent analgesia.

Much of the pain research performed has shown benefits of pre-emptive analgesia. There is a less marked effect of administration of analgesic medication after the noxious stimulus has become established. In a study where flunixin meglumine was administered before laparotomy for correction of abomasal displacement, cows receiving flunixin (2.2 mg/kg IV) had significantly greater rumen contracts during the first 24 hours after surgery as compared with control cows.⁷ This administration of flunixin may not represent pre-emptive analgesia because of the prior abomasal displacement. Another study was designed to investigate the effect of preoperative and 24-hour postoperative administration of flunixin meglumine (1.25 g IV) on postoperative recovery of cows having surgical correction of left displaced abomasum.⁸ In that study, cows receiving flunixin meglumine immediately before and 24-hours after surgery had significantly better appetite, defecation, and milk production compared with cows not having been given flunixin. Recently, meloxicam has been used for pain management in cattle for a variety of conditions. This NSAID has been shown to be effective in mitigating pain of castration and dehorning and the pharmacokinetics suggest that meloxicam should be effective for perioperative pain management as well.³⁰ Clinical experience has been positive with this drug when (0.5 to 1 mg/kg body weight) given orally, every 24 to 48 hours. Future research is needed to more fully elucidate the clinical indication for the use of meloxicam and other emerging analgesic drugs. Based on AMDUCA guidelines, the authors only use meloxicam when pain therapy, and not anti-inflammatory therapy, is needed. In cases of severe, prolonged pain when a pathologic pain state has become established, gabapentin can be administered as a complimentary drug to meloxicam as a multimodal therapy.⁹ The use of gabapentin (10 mg/kg, PO, q12hr) has been useful in cases of deep digital sepsis and septic arthritis as a tool to dampen the exaggerated central nervous response to the limb pain. Multimodal therapy may also utilize opioids (Table 2) and various epidural analgesic strategies (Table 3) to achieve the desired effect.

Advances in Abomasal Surgery

Veterinarians treating dairy cattle commonly diagnose displacement of the abomasum. However, displacement of the abomasum (DA) is a relatively recent phenomenon with respect to the development of the veterinary profession. The earliest reported cases of DA were by Carougeau and Prestat in 1898 and Fincher in 1927, but this disease did not become commonly reported until after the 1940's.¹⁰⁻¹⁶ Prior to that time, DA's either did not occur, were not diagnosed, or were not described as such. Begg reported three cases of left sided displacement of the abomasum (LDA) of which one cow died of peritonitis following surgical reduction of the abomasum and two cows returned to normal after withholding all food for 48 hours.¹² Jones described manual correction of LDA without stabilization of the abomasum in two cows.¹³

The incidence of diagnosis of displacement of the abomasum increased greatly after the mid-1960's and is now an internationally recognized problem of dairy cows. Displacement of the abomasum is commonly referred to as a "disease of high milk production". This statement may be justified in that as dairy cows have been selected for genetic improvement based primarily on milk production, these same cows may have been selected into a high-risk group for development of DA. In 1971, Wallace reported that LDA occurs most commonly in 4 to 6 year old Holstein cows during the first 6 weeks postpartum.¹⁷ Historical factors found to be common among cows with LDA included hypocalcemia (12.4%), ketosis (42%), metritis (41.2%), retained fetal membranes (30.1%), and various stressors (11.7%). Also, LDA appeared to be more common among cows having twins. Physical examination findings common among cows with LDA included metritis (43.5%), mastitis (19%), enteritis (7.3%), and retained fetal membranes (4.8%). Research documented since this study generally has concurred with these findings.

Recently, "two-step" laparoscopic abomasopexy has been described^{18,19}. The "two-step" laparoscopic abomasopexy technique offers advantages of both laparoscopy and blind roll and tack techniques, without the disadvantages associated with the blind roll and tack technique alone. It combines the minimal invasiveness and visual control for abomasal positioning and fixation offered by laparoscopy, and the speed and minimal invasiveness of the roll and tack techniques¹⁸⁻²⁰. The "two-step" technique first involves the laparoscopic guided toggle bar placement within the abomasal lumen through the left paralumbar area in the standing cow, followed by laparoscopic suture retrieval through the right paramedian area while the cow is in dorsal recumbency¹⁸⁻²⁰. Two different one-step laparoscopic abomasopexy techniques have been reported and purported to simplify the use of laparoscopy to accomplish abomasal fixation.²¹ This technique is done similarly to Step 2 of the "two-step" approach except that the cow is placed in dorsal recumbency, and the right paramedian area is aseptically prepared.

The outcomes of the "two-step" laparoscopic abomasopexy compared to traditional right paralumbar omentopexy have been described.²² Ninety-six cows, divided into equal groups, had surgery for LDA. The surgical time for the laparoscopic abomasopexy is 10.2 minutes shorter compared to the traditional laparotomy. Post-operatively, cows that had a laparoscopic abomasopexy had significantly higher feed intakes (roughage +0.61 kg, concentrates +1.24 kg), and their milk yield rose significantly higher (+1.82 kg) compared to the traditional laparotomy group. These investigators suggested that less postoperative pain is experienced by cows that had the laparoscopic abomasopexy; therefore these cows had better feed intake and consequently improved milk yield. Furthermore, this procedure is performed without routine antibiotics, unless concurrent disease (ie metritis) indicated otherwise. This significantly reduced treatment costs and reduced the risk of antibiotic residues compared to the cows that had a traditional laparotomy for correction of LDA. The complications noted for laparoscopic abomasopexy include: premature suture breakage (2 cows), peritonitis (2 cows), and myositis at the abomasopexy site (1 cow).²² In the same study, 1 cow developed an incisional infection where a right paralumbar omentopexy had been performed to correct a LDA. These investigators did not indicate where the suture broke. It is possible either tying the suture around the stent in such a fashion that if one suture broke the other would still hold the toggle and stent in place, or placing a second toggle suture bar at the time of surgery would eliminate this complication. Peritonitis has been recorded as a surgical complication of laparoscopic abomasopexy^{20, 22}. However, peritonitis can also develop secondary to non-surgical complications, such as abomasal ulcers, traumatic-reticuloperitonitis, and metritis. Unfortunately, concurrent diseases were not recorded in either study.

One report from the University of Utrecht in the Netherlands suggested that the "two-step" laparoscopic abomasopexy technique replaced the right paralumbar omentopexy as the standard approach for correcting LDA in 1998.²⁰ These investigators reported on the results of 108

laparoscopic abomasopexies performed under field conditions. The data from 84 returned owner questionnaires are included in this study. The survival rate is 76%, with 57 cows starting a new lactation; 40 cows are not bred, and the fates of 11 cows are unknown. Unfortunately, these results are not compared to their previous results using the right paralumbar omentopexy technique. Peri-operative conditions such as ketosis, fatty liver, retained fetal membranes, metritis, and mastitis remain a challenge to manage post-operatively, and can adversely affect LDA outcomes, regardless of the LDA corrective technique performed. The long term anatomical assessment of the laparoscopic abomasopexy correction for LDA has been reported.²³ Nine weeks post-operatively (6 weeks after the toggle suture had been released), the fixation site between the abomasum and the ventral body wall had stretched up to 15 cm. Therefore, these cows may be at higher risk of LDA recurrence. These investigators suggest that a second toggle suture bar and maintaining the suture longer may produce more permanent adhesions, and consequently less likely for LDA recurrence. Recently, laparoscopic suturing of the abomasums was described to provide a broader, more secure fixation of the abomasum.^{24,25} Although more technically demanding than laparoscopic toggle-pin fixation, this technique may provide for longer term fixation in dairy cows. An advantage of the "one-step" technique over the "two-step" technique is the ability to perform the laparoscopic abomasopexy in the event of a misdiagnosis. This then raises the possibility of performing prophylactic laparoscopic abomasopexies in breeding age heifers. Prophylactic abomasopexies on farms that have high rates of LDA might reduce any adverse events or complications associated with LDA correction in the early post-partum cow.

Many advances in bovine surgery have occurred over the past 25 years including thelscopy, thoracoscopy, epiduroscopy, digital surgery, and cruciate ligament replacement. Although detailed discussion of these is beyond the scope of this proceedings, their contribution to the advancement of bovine surgery should not be discounted. Only through the dedicated efforts of individuals who passionately advocate for the advancement of clinical expertise can we progress. These individuals are some of the finest clinicians and scientists with whom I have ever been affiliated. I am grateful to be able to discuss these issues in highly respected forums such as the World Buiatrics Congress!

Table 1. Analgesic Drugs used in cattle.

Drug	Route	Frequency
Na-Salicylic acid (Aspirin)	PO	Q12-24h
Flunixin meglumine	IV	Q12-24h
Ketoprofen	IV	Q24-48h
Phenylbutazone	PO PO	Q24-48h Q48-72h
Meloxicam	PO	Q24 to 72h
Morphine	IV epidural	Q12h Q24h
Meperidine	SC or IM	
Buprenorphine	IM	Q12h
Butorphenol	SC	Q6h

Table 2. Epidural anesthesia for paralumbar laparotomy.

Drug	Onset of analgesia	Duration of analgesia
Lidocaine 2%	5 minutes	10 to 115 minutes
Xylazine	20 to 40 minutes	2 to 3 hours
Clonidine	2 ug dose: 19 minutes 3 ug dose: 9 minutes	2 ug dose: 192 minutes 3 ug dose: 311 minutes peak effect during 60 to 180 minutes
Ketamine 5%	5ml: 6.5 minutes 10 ml: 5 minutes 20 ml: 5 minutes	5 ml: 17 minutes 10 ml: 34 minutes 20 ml: 62 minutes
Procaine HCl 5%	8 to 20 minutes	45 to 127 minutes mean, 83 minutes

Dairy Herd Health : a look at the veterinarian's changing role and the future of One Health

Émile Bouchard

Faculté de médecine vétérinaire, Université de Montréal

3200 rue Sicotte, Saint-Hyacinthe (Québec), Canada J2S 2M2

emile.bouchard@umontreal.ca

This presentation will focus on preventive veterinary medicine in the area of dairy herd health. I will first examine how this field has evolved over time using a model proposed by the late Dr. Calvin Schwabe. I will then examine the current role of the bovine practitioner in ensuring herd health, especially in the collection of data for use in decision making. Finally, I will look at what the future holds for the veterinarian in dairy practice.

In general, the practice of veterinary medicine has evolved at different rates in different parts of the world. The tools used by veterinarians and the solutions proposed for medical issues also vary depending on the species and type of animal production. A variety of factors – historic, geopolitical, economic and social – come together to determine the role of the veterinarian in any given country.

The history and evolution of veterinary medicine have been the subject of numerous articles and books, many of which have focused on its relationship to human medicine and civilization. One thinker and researcher who has contributed greatly to our understanding of the evolution of preventive veterinary medicine is Calvin Schwabe. Dr. Schwabe was a veterinarian and professor at the University of California, where he founded the Department of Epidemiology and Preventive Medicine, now the Department of Medicine and Epidemiology. He passed away in 2006.

The epidemiological revolution in veterinary medicine

Our profession, like any other, is influenced by advancements in science and technology, along with changing perceptions of ourselves and our view of the world. Schwabe published two pivotal papers on the subject: The current epidemiological revolution in veterinary medicine. Part 1 and The current epidemiological revolution in veterinary medicine. Part 2. Both appeared in the journal Preventive Veterinary Medicine, the first in 1982 and the second in 1993.

In these articles, Schwabe presents a model for understanding the evolution of preventive veterinary medicine. He used the concept of “disciplinary matrix” to represent the research-practice complex underlying disease management in preventive veterinary medicine. Inspired by the ideas of Thomas Kuhn, he defined disciplinary matrix as:

“the complex of self-perceptions, assumptions, underlying theories, long and short-term goals, social and human motives, values and other beliefs, together with the infrastructures, strategies, tactics, techniques and other practices which members of any science currently share.” - Schwabe, 1982

Schwabe identified five “normal” phases in the evolution of veterinary medicine based on knowledge of disease causality. Today's veterinarians will be able to most easily identify with the two most recent phases, IV and V.

(IV) Campaigns or mass actions (1884-1960)

In this phase, the prevailing theory of disease causality is identified as “specific etiological agents” or infectious agents.

The crises that lead to phase V were: recognition of “problem herds” in

campaigns, the demand for economic justification, insidious and “production type” diseases, and the special needs of intensive production units.

(V) Surveillance and selective actions (1960-)

In this phase, the prevailing theory of disease causality is identified as “multiple interacting determinants (agents, hosts, environment, management)”.

Many of us are still familiar with phase IV and the fight against infectious agents. The medical sciences witnessed the introduction of antibiotics during this phase. This discovery had a lasting impact on both human and veterinary medicine, and on associated research in these fields. This phase saw the rise of paradigms centred around, among other things, laboratory diagnosis, vector control, mass communication, mass treatment and education. The passage to a new phase happens when anomalies and crises arise.

A particular phase of normal veterinary science waned when its researchers and practitioners began to encounter anomalies with respect to their currently accepted disciplinary matrix. - Schwabe, 1982

This leads to the formation of new and more adapted paradigms that eventually supplant the old ones. This passage occurs naturally but gradually; while some of us are ready and prepared for the change, others face greater challenges, depending on the expertise available and where they practice. Schwabe noted that changes in activities and perceptions are typically slow to be recognized and that it takes time before they are accepted by a critical mass of researchers and practitioners.

“As one normal veterinary science phase [supplants] another, those aspects of formerly dominant strategies, goals and infrastructures deemed to still possess value [are] retained, but subordinated to those of the new phase..., thus expanding the numbers of tactical permutations and combinations in the veterinarian's totally available armamentarium.” - Schwabe, 1982

This predicted evolution/revolution in paradigm appears at different rates and to varying degrees in different parts of the world. Likewise the role played by veterinarians in fulfilling national or regional needs varies depending on wealth, available technology, public awareness, education level of the population, and food production systems. But whatever form the change takes, it is clear that we always build upon previously acquired knowledge and that the successes of the previous phase are retained. While the emphasis shifts toward new paradigm solutions, the previous phase still exerts its influence. Note that it is veterinary practitioners that are responsible for maintaining cohesion through paradigm shifts, such that the profession can continue to meet its objectives and fulfill its role.

“I predict further, that improved productivity of animals will be as active an area of veterinary medicine-services delivery then, as are animal survival and health maintenance today” - Schwabe, 1993

The observations made by Calvin Schwabe in 1982 were based on changes that were already happening in veterinary practice and research. These changes were facilitated by developments in communication technologies and computer science. The introduction of computers has changed not only many aspects of our daily lives, but also the scientific approach in medicine. Statistics, modeling and information access have all been reshaped by the new technologies. Veterinary medicine is deeply involved in the epidemiological revolution, with risk assessment, evidence-based medicine and now modeling being applied to diagnosis and prevention. Change is happening at different levels of intervention, from the animal right up to the human population.

In 1993, Schwabe was critical of advances made at “herd-level practice,” which he considered as “an ongoing form of field research (surveillance, with appropriate analyses of data) in relation with production”. He blamed “insufficient communication between veterinarians trained in epidemiological diagnosis and those who are not”. This problem still exists, although there has been considerable progress.

Decision making – EVIDENCE BASED MEDICINE – BIG DATA

Faced with multiple risk factors for disease in a herd or population, decision makers must decide which factors to prioritize and how to minimize their effects. When prioritising, many factors have to be considered: herd productivity (economic), animal welfare, product quality, environmental impact and consumer opinion. Decision makers also need data to support their decision making. With the aim of improving dairy herd performance, Canadian researchers and practitioners developed a database to store the health information of individual cows (Bouchard et al., 1991). These data are used to generate information at both the herd and regional level. Data collected in such large databases can also be used to generate information through retrospective studies.

It is important to distinguish between data, information and knowledge. Stand-alone data like “25 kg of milk” does not provide any information unless it is related to stage of lactation or some other value or state. Data and information relate to a specific situation, “whereas knowledge comprises general statements about the world that are useful for explaining, predicting, or guiding future action... and is produced by the application of analytic methods on data and information.” (Ida, 2016). Data analysis using epidemiological methods will give the information and knowledge needed to make decisions and practice evidence-based medicine. “In contrast, big data approaches rarely involve protocol-directed data collection but aim to maximize precision and external validity by the dictum of ‘more data are better than better data’.” (Ida, 2016). Both evidence-based medicine and big data contribute to enlarging and strengthening the knowledge base of clinical medicine.

Models derived from retrospective studies conducted on large populations are already used to predict the risk of an event for an individual or population. In human medicine, modeling is used to predict the risk of heart attack for a given patient based on information about known risk factors. In veterinary medicine, Bouchard (2003) used such an approach to evaluate expected first-service conception risk based on the prevalence of previously identified risk factors combined with their measured effects in dairy herds. Risk factors studied included lactation rank, dystocia, retained placenta, metritis, ovarian cyst, mastitis, lameness, production levels (3 groups), and calving to AI interval (4 groups).

Another example is Bates and Dohoo (2016), who used individual cow records to evaluate risk factors for mastitis. Their retrospective longitudinal cohort study included 18,162 cows from 30 commercial dairy farms on South Island, New Zealand. Risk factors studied were: age, breed, length of dry period, farm, herd size, yield and individual somatic cell count status 30 to 60 days before the end of the previous lactation, rainfall at calving, and number of calvings on the same day. The results of this study could be used to predict expected mastitis level in similar herds.

We need to stress how important it is for veterinarians and producers to collect and eventually combine health record data to obtain valuable information for use on the farm. The knowledge acquired from such data can be used in decision making aimed at eliminating or reducing risk factors through targeted interventions in herd management. Collaboration with researchers is needed for data analyses related to the detection of causality, risk assessment, classification, prediction, modeling and simulation.

LEVELS OF INTERVENTION FOR THE VETERINARY PRACTITIONER

Decisions concerning animal health have to be made at different levels. Veterinarians participate in such decisions for the benefit of the animal, the producer, the transformation industry and, above all, the human population.

The first level of intervention involves the animal and producer. Since the beginning of veterinary practice, practitioners have been confronted with issues at this level. In the beginning, the veterinary practitioner is called

upon to prevent death and obtain an acceptable level of production by re-establishing good health status. The veterinarian’s skills and knowledge in this area have improved over the centuries. In most countries, we now expect veterinarians to keep a written report of their interventions on an animal, including identification, clinical signs, diagnosis, treatment and so on.

The individual health record is considered the basic tool for practicing individual medicine. This record should include all pertinent data on a single animal, rather than simply a list of interventions (diagnosis and treatments) done on the herd. It includes data on demographics (birth, calving, insemination dates), preventive actions, diseases, treatment and production for the animal. By having complete data for each individual animal, the practitioner can evaluate the entire herd.

The second level of intervention involves the herd. Analysing health records provides information on the performance of the herd and the presence of disease in the herd. This is possible thanks to epidemiological and statistical methods. Researchers can develop algorithms to evaluate health status and progression of disease in the herd. Computers and software are the tools of choice for performing such analyses. The veterinary practitioner also has a significant role to play in this area, often being responsible for data entry at the farm level in order to ensure it is complete and complies with quality control programs.

The third level of intervention involves industry and public health authorities. Individual animal and herd information can ultimately be used at the regional and national levels. Data reports on an annual or continuous basis yield valuable information for the industry, while follow-up studies provide information on the impact of interventions. Many countries have drawn up standards and implemented traceability systems. In general, the availability of standardized and validated data is essential for decision makers to intervene at this level.

Note that research can be applied at all of these levels. The existence of research networks, collaborative relationships and access to common databases are all essential in such research.

FUTURE – ONE HEALTH, ARE WE READY?

With increasing consumer awareness and demands, we are seeing an increase in regulation by governments, public organizations and industry. As a result, veterinary expertise, research and knowledge is increasingly being solicited. It is clear that responsibilities and duties must be shared within the veterinary profession and with other professionals. The traditional role of the veterinarian has expanded from simply attending to sick animals to encompass whole new areas of expertise. This specialization has been underway for some time now, such that today the American Veterinary Medical Association (AVMA) recognizes 22 veterinary speciality organizations comprising 41 distinct specialties. Note that not all of these specialty domains apply to farm animals. Most of the specialties in laboratory diagnosis are solicited in food animal production. Still, more communication between the bovine practitioners and the laboratory specialists is desirable for a better integration of the available laboratory diagnostic tests and the development of new ones.

In disease control and health management, decisions have to be made at different levels of organization. At each level, one or more decision makers are involved. Their goals will vary according to their responsibility and objectives, but clearly all decision makers have to be able to communicate effectively in order to be efficient in their interventions.

The concept of “One Health” was introduced almost a decade ago. (As mentioned earlier, “changes in activities and perceptions are typically slow to be recognized”.) As more and more veterinarians work with other professions and scientific realities, they share knowledge and concerns. We now see more veterinarians in the public administration of not only animal, but also human, health. In my country, Canada, we have witnessed the establishment of a new university school of public health in which veterinarians are actively involved (ESPUM, University of

Montreal). Also, the latest veterinary faculty established in Calgary, Alberta is associated with a human medicine school. It integrated comparative health and biomedical research to strengthen the connections between human and animal medicine following the concepts of Virchow in the late 19th century and Schwabe by the end of the 20th century and committed to apply the One Health concept. We also see veterinarians in the Public Health Agency of Canada. This continued and increasing presence of veterinarians in research and public health administration will lead to the creation of better links with veterinary practitioners and the more efficient management of public health.

The collaborative effort of multiple disciplines working locally, nationally, and globally to attain optimal health for people, animals and our environment. - American Veterinary Medical Association, 2008

Networking and animal health databases will gradually come to play an increasing role in the management of public health. In a world of increasing population density and rapid easy communication, veterinarians have to react quickly to get an accurate diagnosis and implement targeted actions. These actions will often need to take place at the farm level, as for example, in the case of pathogen control and the use of antibiotics.

Big data are a distinct “cultural, technological, and scholarly phenomenon” (Boyd) centered on the application of machine learning algorithms to diverse, large-scale data. - Ida, 2016

Basic and applied research have contributed greatly to making diagnostic tools increasingly precise and adapted to field use. But it is important that we veterinarians also contribute to the development and application of new diagnostic tools like laboratory diagnostic tests. We need to establish stronger communication links between research centres, diagnostic laboratories and the field. The task of creating more efficient disease, production and public health systems is a responsibility to be shared between producers, a variety of professionals, decision-makers and the public. It is a state of mind that requires continuous communication, effort and education.

New Zealand Dairy Herd Reproduction: Our role in a new pandemic

Tom Brownlie

Introduction

In the last two decades, our dialogue on dairy herd reproduction has changed as our access to objective herd information has increased. We now largely accept there has been a decline in reproductive performance internationally (Lucy, 2001). Early reports of falling conception rates were published in 1998 in Ireland (O'Farrell and Crilly, 1998) and the US (Butler, 1998) and 2000 in the UK (Royal et al., 2000). It has been speculated that selection for both production and the increased use of Holstein Friesian genetics in herds are primary reasons for this decline (Berry et al., 2013; Evans et al., 2006; Olori et al., 2002) although some historic data is limited by its incompleteness.

Evidence of a decline was first reported in New Zealand in 2006 (Harris, 2006) though there was little evidence of increased use of Holstein genetics (approximately 37% of the national herd) and only a weak link with high milk production when compared to other countries (Grosshans et al., 1997). New Zealand (alongside a growing number of Irish herds) operates a seasonal calving system in order to align peak milk production with peak pasture cover (Verkerk, 2003). New Zealand cows must calve and reconceive during a limited breeding period in order to be retained in the herd. As a result, NZ has had the shortest average calving interval amongst the ICAR countries (<http://www.icar.org>). The proportion of animals pregnant to the first 42 days of the breeding period (the 6 week in-calf rate) is considered the industry standard reproductive outcome measure in New Zealand (Morton, 2000a; Morton, 2010). However, to be measured accurately; all eligible animals in the herd should have a timely pregnancy diagnosis from which the conception date of pregnant animals can be accurately estimated. Early evidence of reproductive decline in New Zealand was made in the absence of accurate pregnancy data (Harris, 2006). Consequently, the decline was identified in the proportion of animals calving in the first 42 days of the two successive breeding seasons (Figure 1). This metric does not account for animals that do not have a subsequent calving in the herd; nonetheless, a marked decline is still evident.

This decline has been the justification for extensive research and focus from industry stakeholders: *Twenty years on, let us reflect on where we have got to?*

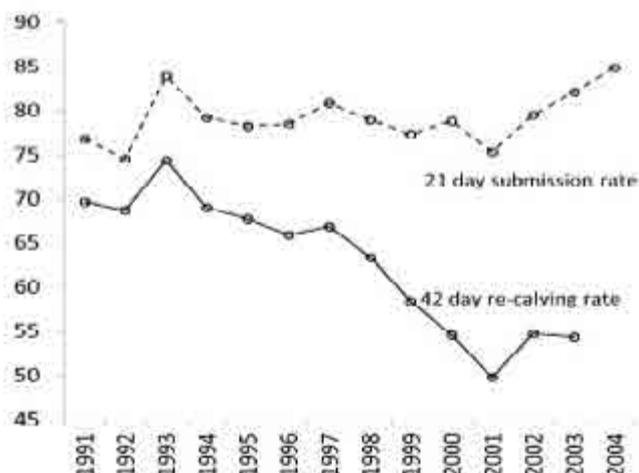

Figure 1. Mean 21 day submission rate (proportion of herd bred in the first 21 days of breeding) and 42 day re-calving rate (proportion of herd calving in the first 42 days of calving periods) of a sample of 221,224 cows from the LIC Sire Proving Scheme database between 1990 to 2004 (Harris 2006)

Advances over the last few years

Three key changes in the dairy industry have had a direct or indirect impact on dairy herd reproductive performance in New Zealand:

- i) The launch of a national extension programme (InCalf) for dairy farmers,
- ii) the addition of a fertility trait in the National Breeding Value Index
- iii) the accelerating use of technology on farm creating broader and deeper data streams.

i. A National Extension Programme: InCalf

InCalf is an extension package of resources, tools and training for both dairy farmers and their advisors. It was originally developed in Australia (Britton et al., 2003) and adapted for the New Zealand system in 2007 (Blackwell, 2008). InCalf offers advisors a structured framework to be used at critical times throughout the seasonal dairy year and focuses on eight key risk factors considered important for reproductive performance (Morton, 2000b). Its release was widely promoted in the national agricultural press and through stakeholder roadshows and the advisor training has been well attended. There are currently 550 trained InCalf advisors (www.dairynz.co.nz), of which approximately 75% are veterinarians. If we accept that only predominantly large animal practitioners have undertaken the training then over two thirds (68%) of all New Zealand large animal practitioners are also InCalf advisors (Anonymous, 2013b).

Following its release, the effect of participation in the InCalf programme was quantified using a large scale multi-centre multi-year randomised controlled study (Brownlie et al., 2015a). The study evaluated InCalf primarily on change in the 6 week in-calf rate, a key performance indicator of InCalf. Participation in the programme was associated with a modest but sustained 2% improvement in 6 week in-calf rate over herds that did not participate. In order to better understand the process behind this effect, the study quantified the effect of participation on key risk factors (Brownlie et al., 2015b) and conducted extensive interviews to determine the attitudes, values and goals of the participants (Brownlie et al., 2011). This paper will consider each of these steps from a New Zealand perspective.

Figure 2: Simplified schematic of the proposed pathway to achieving change in an end-result through modifying or removing risk factors (in a farming context this is commonly adopting new or modified existing management practices) as a result of changes in Knowledge, Attitudes, Skills and Aspirations (KASA). The process is adapted from behavioural theory and comprises the top three tiers of Bennetts Hierarchy of Evaluating Agricultural Extension (Bennett, 1975)

ii. Genetics: Fertility BV

Alongside the national extension strategy, a Fertility Breeding Value was incorporated into the New Zealand Breeding Value in 2002 (Harris, 2006). The Breeding Value is a genetic score based on nationally available data that compares certain traits within contemporary daughter groups and years, to help support breeding decisions. The Fertility Breeding Value is based on reproductive traits including being bred in the first 21 days of the breeding period, calving in the first 42 days of the calving period, body condition score in the first 60 days of lactation and milk volume. The traits are identical to those used to assess herd performance and hence it is inappropriate to incorporate Fertility Breeding Value in models of management practice. However, breeding selection should be acknowledged as a hidden variable inherent in models of the effect of management practices over time. The Fertility Breeding Value has low heritability (estimated at 9% heritable trait when associated with its predictor variables; Harris pers comm); but the effect is cumulative over time (Bowley et al., 2015).

iii. Technology:

The contribution of technology cannot be ignored when considering change in the dairy sector. Its adoption is leading to a pandemic of data largely driven by automated collection of behavioural, biological and environmental data. Data capture is intrinsic in most new technology yet on its own, can quickly become obsolete if not integrated with other streams of data. In technology terms, longevity requires integration. Commendably, some veterinary businesses are already growing off the back of aligning these data (Infovet (Zoetis Inc.) and VetImpress (Farmvet Systems Ltd.).

Figure 3 illustrates the increase in pregnancy testing events that are now captured in the LIC proprietary database in New Zealand. These data are recorded on farm through multiple mobile sources some of which are competing companies. The pressure to integrate in this case arises from the requirement that data be available on the predominant on-farm software platform in New Zealand in order to have perceived value.

Integration often occurs before any value is added to the data through expert interpretation or analysis. The challenge for rural professionals is how and where to add this value.

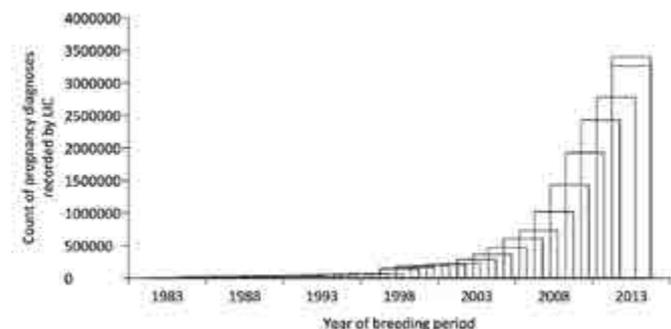

Figure 3: Annual increase in national pregnancy diagnosis recording evident in the LIC proprietary database (LIC, New Zealand).

1. End Result: improving 6 week in-calf rate

Important key performance indicators for reproductive performance in seasonal systems are commonly proportions (e.g. the incorrectly termed 6 week in-calf rate). The challenge when calculating these is ensuring that both the numerators and denominators are precise and comparable.

By applying consistent rules to the New Zealand national dataset, a unique picture of the reproductive performance for all herds in can be described. For this purpose, 39,379,095 breeding's, 29,337,967 calving's and 18,128,116 pregnancy diagnoses were used to describe reproductive performance in 12,713 distinct herds from 2009 onwards. Animals that ceased contributing any events yet had no removal record were right censored in their last year of contributing (comprising approximately 12% of the national dataset). The results suggest that from 2010 onwards there has been a modest, incremental improvement in the overall reproductive performance of New Zealand dairy herds (Figure 4 a-c).

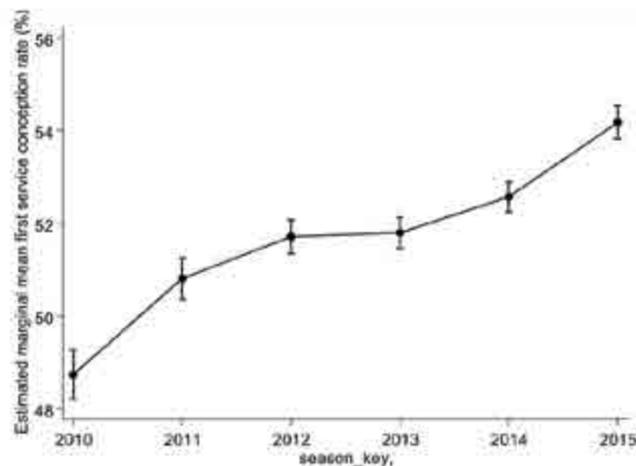

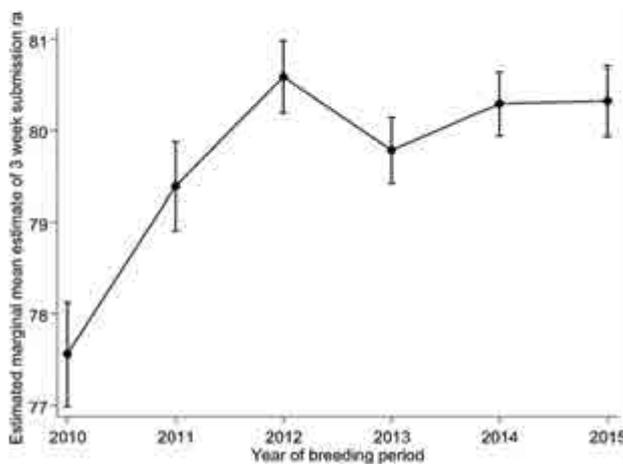

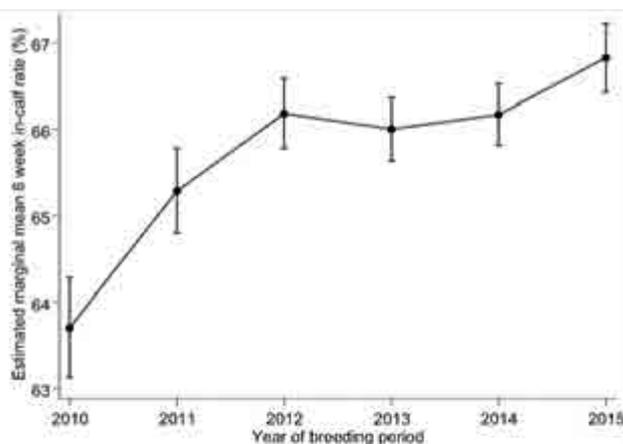

Figure 4. a –c. Estimated marginal mean outcomes from three herd-year level linear regression models of 6 week in-calf rate, 3 week submission rates and conception rates for New Zealand dairy herds eligible to generate cumulative pregnancy life tables (i.e. ≥80% of herd having an aged pregnancy test or confirmed not pregnant under 170 days after the start of breeding)

The economic benefits of a high 6 week in-calf rate are relatively simple to estimate and make the in-calf rate an appropriate target for overall herd performance. However, to benchmark herds on this measure alone is insensitive to the levels at which risk factors affect reproductive performance (Xu, 2003). Variation in performance occurs at region, herd and cow level in different amounts. To improve performance, effort should be concentrated where greatest variation is found.

To illustrate this, data from the New Zealand National Herd Fertility Study were used to create multilevel mixed-effects logistic regression models to determine (a) 6 week in-calf rate, (b) 3 week submission rate and (c)

	Intraclass correlation coefficient (95% CI) as a percentage		
	6 week in-calf rate	3 week submission rate	First service conception rate
region	<0.01(<0.01 - <0.01)	0.07 (<0.01 - 33.66)	0.02 (<0.01 - 12.04)
herd within region	3.30 (2.51 - 4.21)	7.50 (5.87 - 9.53)	2.10 (1.60 - 2.76)
cow ^a	96.75	92.50	97.88

Table 1. Intraclass correlation coefficients presented as percentages from three multilevel mixed effect logistic regression models of three measures of reproductive performance where herd and region level were fitted as random effects from data on cow-years enrolled in the New Zealand National Herd Fertility Study during the 2009/10 and 2010/11 years. Repeated measures between years was removed by including the year as a fixed effect in the models

^a residual variance found at cow level was derived by subtracting coefficients from region and herd level from one

first service conception rate, the latter two being considered the drivers of in-calf rates. No further covariates were included in these models. Intraclass correlation coefficients were derived from these models (Table 1). In mixed effect models, intra-class correlation coefficients measure absolute agreement between outcomes at nested levels within the model. Conditional on the year, reproductive performance measures barely correlate within the same region, and only very slightly within the same herd and region. The remaining residual variance therefore resides at cow level. Thus to improve herd or regional reproductive performance, identifying risk factors for individual cows will be the most effective route. Advisors should be aware of cow-level risk factors and which ones can be measured and improved.

2. Risk factors

Cow-year-level risk factors affect the reproductive performance of a cow within a lactation (such as periparturient mastitis or calving date relative to the start of the breeding season) but can also affect herd-level reproductive performance, if a substantial proportion of the herd is affected (Evans and Walsh, 2011; Xu, 2003). However, the relationship between cow-year-level risk factors and reproductive performance cannot simply be inferred at a herd-year-level without the risk of atomistic fallacy (for example, the effect of Jersey breed as a cow is not necessarily transferable to a herd level as it is easily confounded by the age structure of the herd). Furthermore, some cow-year-level risk factors are a consequence of the same management factors at a herd-level, for example, proportion of herd meeting pre-mating body condition score targets and herd mean milk protein at first herd test are both reflective of herd nutrition and to a lesser extent, genetic status. Many of these factors are also confounded by cow-level factors (e.g. cow breed) and certain cow-year-level risk factors (e.g. cow age and calving date relative to the start of the breeding period). So some factors are associated with reproductive performance measures directly as well as interacting with other risk factors (e.g. association between different cow breeds on milk production parameters).

In New Zealand, the National Herd Fertility Study provided accurate data on a wide range of risk factors from 134,880 cow years from 2009 to 2011 in four dairy regions of New Zealand (Brownlie et al., 2014). Table 2 presents the outcomes of the same multilevel mixed effects models presented in Section 4, with addition of key risk factor following reverse stepwise modelling. Table 4 uses many of the same variables summarised at a herd-level. These results demonstrate that multiple factors including age, breed and date of calving relative to the start of the breeding program strongly affect reproductive measures at both levels, yet other factors do not transfer their effect to the herd-level, e.g. proportion of calving's given assistance or cows treated for mastitis during breeding. Interestingly, milk production parameters (milk protein percent and milk fat (kg)) explain greater variation in reproductive performance than body condition score alone.

So, given this wealth of information and the growing access to clear messages; *how has the New Zealand veterinary profession responded?*

3. Knowledge, Attitudes, Skills and Aspirations

If we follow the framework for behavioural change that we introduced in Figure 1, we should next examine the attitudes, priorities and perceived constraints of decision makers on these herds (Fishbein, 1975). However, let us instead look to rural professionals (i.e. veterinarians) who advise these decision makers. Veterinarians are consistently identified as the key advisors on herd reproduction and health (Burke et al., 2008) and for over 20 years the veterinary profession has been encouraged to prioritise formal advisory work (Mee, 2010). Today, as agriculture moves across the technological epoch, the imperative to adapt will be due to new pressures: Smart algorithms are rapidly evolving that will automate on-farm decision making and this will most likely erode the veterinary role as custodian of reproductive performance.

The growing importance and depth of information being collected on-farm means that we will invariably have to become consumers of these data in order to remain relevant.

We will end up paying for access to these data unless we can trade our expertise to become part of this process. Where it becomes likely that we will need to invest, we need to know how to make the investment work well for us. Unlike other challenges the profession has faced, this one presents many opportunities.

As part of an engagement process, sixteen purposively selected veterinarians from across New Zealand were inducted into a Design Thinking process where the future role of veterinarians in the Data Value Chain (Gustafson and Fink, 2013) was explored. Design Thinking is an established, structured design process that uses informal interviews to create concise statements of participants' perceived constraints and opportunities (Kimbrell, 2011). Participants were given access to data stored in the LIC proprietary database and asked how to generate value from these data.

Four key statements were described using this process:

1. Data that vets collect on farm needs to be integrated with farmer software in order to be valuable.

Currently, many veterinary practices across New Zealand invest a considerable sum in a software service principally to upload pregnancy diagnoses onto farmer software and thereby increasing the value of their diagnostic service. Study participants felt that this investment was justified if it simply maintained a lead in a highly competitive market.

2. Benchmarking key performance indicators is the starting point of most advisor conversations

Participants felt that a key role of reproductive data was to provide benchmarking. Benchmarking provided a motivational tool for farmers and vets; provided evidence of change and was used as a common starting point for advisory work. Local benchmarks or benchmarks from similar farming systems were considered the most engaging although not easily available.

3. Allow veterinarians to perform exploratory data analysis will create value

Exploratory data analyses are normally embarked upon in response to poor performance. It is a service offered by an advisor to identify specific gaps in herd performance to target professional intervention.

4. Generate a tangible chargeable product to justify the cost of data

Most participants did not have clear plan to generate sustainable income from the data in which they had invested. Most participants favoured customised reports for herd owners if they were not time consuming to prepare. However, if these were standardized and inflexible, their long term use would diminish. Participants felt that data access should increase their competitive advantage and that they were prepared to continue investment in employee upskilling once greater access to data was secured.

Confidence around the role of data in participants businesses was highest in the first two statements but diminished in the second two. This reinforces the perception that the veterinary industry does not have a clear business case yet for the use of the large amount of data being generated. Fortunately, veterinary advice remains a valuable commodity. Veterinary advice on reducing reproductive risk factors augments automated data collection and empowering veterinarians to integrating with these systems is beneficial to more than just veterinarians. It is now up to the veterinary profession to ensure that we are willing to participate and even guide this new and exciting technology.

Conclusions

The reproductive performance of New Zealand dairy herds has been a focus for many industry stakeholders for almost 20 years. The investment in science, extension and technology is likely to be reflected in the incremental improvement in performance. However, a fundamental shift is still required if New Zealand stands any chance of reaching its industry target of a national average 78% 6 week in-calf rate in the next 4 years (Anonymous, 2013a). This target seems unachievable unless we return to cow-level management as our best strategy. Armed with objective information on clients' herds, veterinarians have a key role as advisors.

The challenge for the profession is to become recognised for their position in this data value chain: We must engage with other people in the farmer network and become innovative and collaborative rather than hope that the status quo prevails. After all, we ought not to use data only as a *drunken man uses lamp posts – for support rather than for illumination**.

Health Planning for the Beef Cow Herd

G Caldow BVM&S, MSc, CertCHP, DipECBHM, MRCVS, FRAGS

SAC Consulting Veterinary Services, Scotland.

Introduction

The planned approach to managing animal health through analysis of production data and risk assessment has supported intensive livestock production systems for decades (Blood, 1979). The veterinarians' skill and knowledge has given them a pivotal role in supporting efficient food production from our livestock whilst safeguarding their welfare. This relationship has been well-developed in those sectors that have driven to improve efficiency, but is poorly developed in the beef cow industry. Although production from the beef cow herd is an important area of agricultural output throughout the world, this production system is inefficient and long term profitability is rarely achieved without the help of direct payments (Deblitz 2012). There is a higher demand for maintenance per kilogram of output than any other livestock sector arising from the high maintenance costs of the parent herd (Morris and Smeaton 2009) and the long period from birth to slaughter. Relative profitability has been shown to be closely related to physical output, but estimates of the average number of calves weaned expressed as a percentage of cows mated varies around 87% in most years in Great Britain (QMS, EBLEX, and HCC) and an average of 82% has been quoted for the New Zealand herds. In contrast targets of 94% in Great Britain (MLC 1998) and 92% New Zealand (Morris and Smeaton 2009) have been cited.

Nevertheless the beef cow's ability to use poor quality herbage to produce and rear a calf ensures that beef cow production has a place in areas where there are limited alternatives for land use such as in the tropical rangelands of Queensland (Gleeson et al 2012) or the temperate rangelands of North America. Furthermore beef cow herds also complement more efficient production systems such as fat lamb production in New Zealand where the cows can be used to improve pasture management (Pleasants et al 1991) or in areas of arable production where the by-products, particularly from cereal crops, can be fed to cows.

A further area of concern stems from this biological inefficiency: livestock production is a significant contributor to greenhouse gas (GHG) emissions and ruminants have a particularly high impact (Gill et al 2010). In beef cow production systems that use poor quality forage the proportional output of methane is higher and while large within breed variation is seen in both feed conversion efficiency and GHG emission it remains difficult to mitigate this environmental impact to any degree without improving production efficiency (Nguyen et al 2013).

Improving the efficiency of production will not only increase the gross margins of producers, but will reduce the GHG emission per kg of meat produced from the beef cow herd (Harrison et al 2016).

Improving the efficiency of beef cow herds.

Output efficiency for beef cow herds is measured as kilogram of calf weaned per kilogram of cow mated and an ambitious target is 0.5 kg per kg per year. The elements of this are the fertility of the adult herd, the ability of the calf to survive birth and to maintain its viability thereafter and the ability of the calf to achieve growth rates in excess of one kg per day on a combined ration of milk and grass. The cow should be able to use forage efficiently and to store additional energy as fat to reduce feed requirements through winter or dry seasons and additionally to exhibit strong maternal traits. For the effective use of resource cows should be reared to produce their first calf at two years of age, in all but the most challenging situations and to continue to produce a calf each year for nine years when mated for a restricted period of two months.

It is important to consider if enough is understood about the limiting factors to ensure these can be managed to promote efficient production? Whilst suckling does add two weeks to the time to onset of pulsatile luteinising hormone release), postpartum anoestrus in beef cows in the European situation (Busch 1998) and in North America (Werth 1996) is not a barrier to achieving the reproductive targets. The impact of energy supply on the reproductive function of the cows and on the interaction with growth in the young cows has been well described (Short et al 1990). Managing the cows' ability to use the cyclical supply of forage to store nutrients in body reserves has been facilitated by body condition scoring systems (Thompson et al 1983), creating a tool that can be used to achieve target body condition score at calving and breeding thereby ensuring that energy deficiency does not impair the return to oestrus. The other element of good herd fertility is the bull and sound methodology exists for assessing reproductive capacity in the bull (McGowan 2007).

The cow should also rear her calf and produce sufficient milk to allow the calf to achieve the growth target. Dystocia and calf mortality is the second largest area of loss and enough is already known about the factors that contribute to this (Waldner 2014). Working to reduce the occurrence of dystocia and ensuring the cows are fed to reach the target condition score will have the valuable consequence that sufficient quality colostrum will be available and that most of the calves will suck well and absorb sufficient immunoglobulin to mitigate the risk of neonatal disease. Infectious disease impacts on fertility and on calf survival and growth. Disease control is the final essential element required to promote beef cow production efficiency and enough is known to prevent disease incursion; to control contributory factors and to promote specific immunity.

These principles can be translated to simple messages. In Great Britain this has been done by creating a five point plan (QMS 2014) (table 1).

Health Planning

Health planning provides a framework for the delivery of veterinary expertise to the animal production unit to make best use of the resource for the benefit of the animals and the producers. Health planning should be the ideal way to improve production efficiency in the beef herd. In Great Britain cattle health plans were a formal document (Pocock 2004) that detailed the diseases that a herd were exposed to and the treatments and preventive actions that would mitigate the disease risks. The plan was reviewed each year. This was adopted by the farm assurance systems and a health plan became a mandatory requirement. The first problem with this was that the focus was on written detail on disease and not on analysis of production and disease occurrence and the consequent losses. The second drawback was that production of the document was seen as an end in itself and once produced the document was no longer referred to.

The challenge was to move from the static document on disease control to a dynamic process that embraced process management techniques to analyse production and identify areas for improvement. The collection of the requisite data to generate the key performance indicators is not a problem for most production systems, but the statutory requirements for the European beef cow herds is to record the number of animals on the farm, to register births within 27 days and to register deaths and movements off the farm as they occur. There is no encouragement to collect any other data. It is difficult to determine the key denominator, which is the number of females in the herd that were mated. Furthermore there may be no record of the calves that died before they were registered. To overcome these deficits we produced an approach to recording events in the herd to generate the key performance indicators, namely the percentage of calves weaned, the percentage of cows that calved, the percentage of calves born, the percentage of calves that died (at different stages of their life) and the percentage of cows that calved in the first three weeks of the breeding season and embedded this within a web-based database (SAC 2016).

The concept requires the beef cow farmer to enter data into the system; detail the current herd preventive actions and treatments and list any disease problem thought to be present on the farm. This can reduce the time required by the herd's veterinarian, as veterinary time need only start once the preparatory data has been entered. However, particularly given the seasonal nature of the production cycle the participating farmers enter the data so infrequently that they rarely establish familiarity with the software and find the process daunting. For many participating herds the veterinarian enters the data and thereby adds unnecessary cost to the process.

Hazard analysis critical control point (HACCP) methodology has been used in the delivery of veterinary advice to the dairy herd (da Silva et al 2006). This links risk management principles to operational management. and is appropriate because of the immediate public health aspects of milk production as compared to the sale of weaned beef calves, but by taking HACCP and aligning this with classic risk management methodology (OIE 2007) a methodology that is well-fitted to assessing productivity and managing risk within the beef cow herd can be constructed (table 2). This format allows the veterinarian to assess the risk of a particular hazard to the herd productivity, whether it is an infectious agent or a factor that may impact negatively on reproductive performance. Central to risk analysis is communication and prioritisation. In the case of health planning for the beef cow herd the identification of the main risks and discussion with the farmer allows effective prioritisation to achieve the greatest gain in a production system where financial resource is likely to be severely limited.

The focus of this discussion has been on improving output to increase the biological efficiency of the beef cow herd, but there are other important inefficiencies within these systems. While access to medicines varies from country to country there are many licensed products and feed additives that are used on farms without the veterinary surgeon being aware of their use. In the British situation there is considerable potential for the incorrect use of anthelmintics and mineral supplements. By requesting the farmer to detail this use the opportunity is created for the veterinarian to provide the advice to rationalise the use of these products such that the cost savings from this may exceed the professional fee for the health planning service.

Despite a powerful rational for health planning the gains have been slight and while herds in the top quartile show a level of performance that exceeds the target there remains relatively few herds participating in this approach. Cattle farmers in Britain have traditionally been slow to adopt health management strategies that have been shown to improve profitability. The improvement in milk quality did not result from a widespread acceptance of the simple messages on mastitis control, but followed payment penalties for total bacterial and somatic cell counts (Booth 2000). Indeed there may be a high level of scepticism or unwillingness on the part of the majority of farmers and veterinarians to be convinced that change is possible or that health planning is a tool that can be used to achieve improvement.

It may be that it is too difficult to record and engage with the process in the modern beef cow herds where the number of cows per herd has increased as the number of workers has declined. To overcome that barrier a different approach to recording events is required. Information and events should be recorded once and the information then is available for multiple applications, easing the workload rather than adding to it. There are statutory requirements for recording births deaths and movements and for recording medicines. Creating a hand held electronic solution to make use of herd animal inventory and medicine inventory whilst tying this to other events such as birth of dead calves and disease incidents and treatments is achievable. Mobile telephone technology now provides effective solutions for this data collection challenge.

Apart from the efficient use of data a further advantage lies in moving data analysis into real time allowing notification of events to the veterinarian. Clusters of deaths or events such as assisted calvings that may not have

triggered a call to the veterinary practice can be communicated through the system and allow early contact and discussion.

Conclusion: Produce from beef cow herds makes up an important part of the livestock output in many countries using land that has limited alternative uses as well as complementing more efficient production systems. The profitability of beef cow herds is low, stemming from low levels of biological efficiency, but also because the average level of productivity is low. There is sufficient understanding of the process and its limiting factors to manage herds to achieve outputs of at least 94 calves reared per 100 cows mated and yet the average output is consistently very much less than this. There is therefore a powerful rationale to improve the efficiency of production in order to both increase the returns from a poorly profitable enterprise and to reduce the greenhouse gas emission per kg of calf sold. As has been argued for decades, the veterinarian is well-placed to provide a service that will help achieve these goals through health planning and it is troubling that more has not been achieved. There is now a clear understanding that for health planning to be successful the process should embody data analysis and risk management and make the most efficient use of technology. It is envisaged that this will be achieved through the collection of data at the point at which events occur using hand held devices such as mobile phones with aggregation of data on a web-based database that facilitates health planning.

Sustainable Agriculture

Jude L. Capper, PhD

Livestock Sustainability Consultancy, Harwell, Oxfordshire, OX11 0HH, UK

Introduction

Agricultural sustainability (specifically livestock system sustainability) is one of the most highly-debated issues within food production. The sustainability concept may be partitioned into three components: environmental impact, economic viability, and social acceptability (United Nations, 2005). For a region, industry or system to achieve sustainability, all three components must balance - if one factor is misaligned, ignored, or the sole focal point, then long-term sustainability is impossible. Livestock provide high-quality food products in conjunction with a myriad of associated economic and social benefits to global communities. Nonetheless, the question is often raised as to whether milk and meat consumption is unsustainable. The majority of current research has focused upon the environmental component of sustainability, which given the positive correlation between resource use and economic viability, may also encompass farm profitability. This paper therefore concentrates primarily on the environmental aspect; with the understanding that reduced resource use also has positive economic and social impacts.

The Environmental Impact of Livestock Production

Environmental impact is a multifactorial issue. Although it is often discussed with sole reference to greenhouse gas (GHG) emissions, resource scarcity (specifically water, land, inorganic fertilisers and fossil fuels) may be argued to have a greater immediate effect upon food production. Nonetheless, the majority of studies to date have concentrated on GHG as the sole arbiter of environmental impact. Agricultural GHG emissions were estimated by Bellarby et al. (2008) to account for between 17% and 32% of all global anthropogenic emissions, with reports by the FAO (2006) and the World Watch Institute (Goodland & Anhang, 2009) concluding that animal agriculture contributes 18% or 51% of GHG emissions respectively. Global averages are somewhat meaningless, however, as they are not representative of any specific region or system and thus offer little opportunity for practical mitigation. For example, dairy production contributes ~2.7% of worldwide GHG emissions, with average emissions of 2.4 kg CO₂-eq/kg FPCM (fat and protein-corrected milk) at the farm-gate (FAO, 2010), yet significant regional variation exists, with values ranging from 7.5 kg CO₂-eq/kg FPCM in sub-Saharan Africa (average milk yield of 300 kg/y) to 1.3 CO₂-eq/kg FPCM in North America (average milk yield of 8,900 kg/y). It appears therefore that a negative correlation exists between milk yield and carbon footprint - as productivity increases, GHG emissions decrease per unit of milk.

The environmental mitigation effect of improving productivity is conferred by the "dilution of maintenance" concept (Capper, 2011a; Capper et al., 2008). Regardless of species, every animal within a herd or flock has a daily maintenance nutrient requirement plus an extra nutrient requirement for productivity (milk, meat or egg production; pregnancy and lactation). As productivity increases, the proportion of daily energy allocated to maintenance decreases and the maintenance requirement of the total animal population decreases. The nutrient requirement can be considered a proxy for resource use. As production system intensity increases, productivity improves, thus "intensive" systems tend to use fewer resources and have lower GHG emissions than "extensive" systems (Capper, 2011b). However, these improvements are not always well understood by consumers who often have a ideological view of the perceived advantages of historical small-scale agrarian systems compared to modern agriculture.

The dichotomy between popular perception and agricultural reality is exemplified by comparing the U.S. dairy industries in 1944 and 2007, as reported by Capper et al. (2009). A four-fold increase in milk yield per cow over this time allowed for a 59% increase in total milk production (53 billion kg in 1944 vs. 84 billion kg in 2007) whilst the national dairy herd was reduced from 25.6 million to 9.2 million cattle. This reduced feed use by 77%, land use by 90%, water use by 65% and conferred a 63% decrease in GHG emissions per kg of milk (Capper et al., 2009). Similarly, through improvements in genetics, nutrition and management between 1977 and 2007, the U.S. beef cattle industry increased average slaughter weight (607 kg in 2007 vs. 468 kg in 1977) and growth rate (1.18 kg/d in 2007 vs. 0.72 kg/d in 1977) which resulted in the total days required to raise a beef animal being reduced from 609 d (1977) to 485 d (2007). These gains resulted in considerable reductions in feed (19%), land (33%), water (12%) and GHG emissions (16%) per kg of beef over the thirty-year time period (Capper, 2011a). The U.S. pork industry has also reduced both resource use and GHG emissions per unit of pork over the past 50 years through similar mechanisms to those exhibited by the U.S. beef industry, i.e. increasing the number of hogs marketed from 87.6 million in 1959 to 112.6 million in 2009 (a 29% increase), from a breeding herd that has decreased in size by 39% over the same time period (Cady et al., 2013). Similar improvements have been demonstrated in many developed livestock industries, although their impacts are only now being quantified with reference to resource use.

Milk and meat from extensive forage-based production systems are attractive to the consumer wishing to buy food from "traditional" production systems, yet often use greater quantities of resources. Reduced growth rates and slaughter weights in combination with augmented methane emissions from a forage-based diet increase GHG emissions from 16.2 kg CO₂-eq/kg liveweight for feedlot-finished beef to 19.2 kg CO₂-eq/kg liveweight for pasture-finished beef according to Pelletier et al. (2010). If current intensive U.S. beef finishing systems were replaced by a wholly forage-based system, it would require an increase of 52 million ha of land to maintain current U.S. beef production and the increase in carbon emissions would be equal to adding 25.2 million cars to the road per year (Capper, 2012). Producing milk in organic production systems was found by Capper et al. (2008) to confer a 13% increase in GHG emissions per unit of milk (U.S.) and by Cederberg and Mattsson (2000) to increase GHG emissions by 15% (Sweden). By contrast, a comparison of organic and conventional poultry systems by Boggia et al. (2010) reported that organic poultry systems exhibited superior environmental performance.

Further Opportunities to Improve Sustainability

Management practices may be adopted to reduce specific environmental impacts, e.g. soil testing, installation of anaerobic digesters, or recycling water on-farm. However, a greater mitigation effect may be achieved through whole-system approaches that improve animal productivity and allow livestock to perform to their genetic potential. If a livestock system working at optimal efficiency would produce a set quantity of milk or meat in a given time, every loss of productivity within the system will reduce the milk/meat yield and increase both economic cost and environmental impact per unit of food produced. One major advantage of productivity-based approaches is that they are irrespective of system (e.g. intensive vs. extensive, conventional vs. organic), operation size or region, thus can be implemented globally according to resource availability and market considerations.

The aforementioned gains in milk, meat and egg productivity have had tangible results, however, in many livestock industries, animal bodyweight has increased concurrently with productivity gains, therefore daily resource use and GHG emissions per animal have increased (Capper, 2011a; Capper et al., 2009), although environmental impact per unit of food produced is reduced. If bodyweight in the supporting herd could be reduced without a loss of productivity, environmental and economic gains would result. Within dairy production, Capper and Cady (2012) reported that producing cheese from Jersey cattle (average

mature liveweight 454 kg) vs. Holstein cattle (average mature liveweight 680 kg) considerably reduced both resource use and GHG emissions. Within beef production, if mature beef cow bodyweight were reduced from 703 kg to 486 kg while maintaining the final carcass weight of the offspring, GHG emissions per unit of beef would decline by 13% (Capper, 2013b).

The introduction of genetic selection tools over the past century has allowed for greater rates of genetic improvement, however, these may have negative impacts, e.g. the conflict between increased milk yield in dairy cattle and declining fertility rates. Garnsworthy (2004) demonstrated that restoring fertility levels to those seen in UK dairy cattle c. 1995, or improving them to ideal levels, reduced methane emissions per unit of milk through a reduction in the number of heifer replacements required within the herd and thus a decrease in the herd maintenance requirement. Within the US, 89% of cows bear a live calf each year (USDA, 2009), and this number declines to between 50-60% in the extensive systems characteristic of Brazil, Argentina and Chile. Given that the cow-calf (suckler) operation contributes up to 80% of GHG emissions per unit of beef (Beauchemin et al., 2010) management practices and technologies that improve pregnancy rate offer significant opportunities. Capper (2013a) demonstrated that if calving rate increased from 60% to 100%, land use declined from 3.61 ha to 2.54 ha, water use from 682 x 103 litres to 508 x 103 litres, GHG emissions from 7,945 kg to 5,459 kg and feed costs from \$1,924 to \$1,412 per 363 kg beef carcass.

Is Vegetarianism the Answer?

Campaigns such as "Meatless" or "Meat Free" Mondays have been adopted by consumers who perceive that reducing meat consumption will improve their health or reduce their personal environmental impacts. Tobler et al. (2011) suggest that reducing meat consumption on a global scale would meet with considerable opposition, as consumers who regularly consume meat are unlikely to change their dietary habits. However, a recent analysis by Säll and Gren (2015) demonstrated that imposing a tax on meat and dairy products could potentially reduce environmental impacts of Swedish livestock production by 12%.

The average UK inhabitant consumes 79 kg of meat per year (AHDB, 2013), and meat plus dairy production is cited as contributing ~6% to annual UK GHG emissions (Department of Energy and Climate Change, 2016). To take the simplistic view that a one-day per week reduction in meat consumption would cut animal production by one-seventh, if every one of the UK's 65 million inhabitants adopted such a dietary change, the projected annual reduction in national GHG emissions would be less than 1%. Moreover, livestock production does not simply produce animal-source foods, but also multifarious by-products, including hides, fertilizer, tallow and pharmaceuticals. It is not yet clear what environmental impacts would result from replacing manure with inorganic fertilizers; pharmaceutical ingredients with synthetic alternatives; or from the disposal of the many by-products from human food and fibre production currently consumed by livestock (e.g. sugar beet pulp, maize gluten, cottonseed meal). Gill (1999) estimated that 37 kg of by-product feeds suitable for livestock are produced from every 100 kg of plants grown for human food.

The relatively low feed conversion efficiency of plant-based feedstuffs into animal proteins is likely to remain one of the biggest arguments against the omnivorous diet; yet is also one of the major advantages of livestock production, specifically production of high-quality proteins from human-inedible forages within ruminant systems. When comparing resource use for various human diets, Fairlie (2010) noted that converting from a conventional omnivorous diet to a vegan diet would reduce overall land use, yet the reduction was almost entirely confined to pasture land used for grazing. The quantity of land used to produce annual crops was increased in Fairlie's vegan scenario both due to the lack of animal manures for fertiliser (therefore lower crop yields) and the need to provide vegetable-based fats and oils for energy within the

human diet. Globally, over 3 billion ha of pastureland are currently used to raise livestock, yet only a small proportion of grazed pasturelands are suitable for food crop production due to terrain, water or nutrient restrictions.

Consumer Perceptions of Sustainability

Although survey data overwhelmingly concludes that price, taste, convenience and nutrition are the major factors affecting purchasing decisions (Simmons, 2009; Vermeir & Verbeke, 2006), these are still dependent on the product being morally or ethically acceptable to the consumer. Greater emphasis is being placed on non-tangible attributes such as "environmentally-friendly" or "natural" foods – indeed Robinson and Smith (2002) reported that 52% of consumers showed interest in purchasing "earth-sustainable foods", and White and Brady (2013) reported that consumers would pay a 4% premium for beef products perceived to have positive effects on environmental impact, which increased to an 82% premium for products with a combined environmental and health benefit. However, cited interests only translate into a change in buying behaviours for a small segment of consumers, hence the relatively small market share for niche systems such as organic, local or natural foods at present (Vermeir & Verbeke, 2006).

Maintaining and improving sustainability in the face of a consumer market that is increasingly skeptical about food production transparency and management practices is a considerable challenge. According to a recent report from SHS FoodThink (2013), only 22% of consumers believe that the agricultural industry is transparent about their practices, yet 53% of consumers trust farmers (compared to academics at 51%, media at 21% and politicians at 8%). Therefore the livestock industry has a considerable opportunity to explain management systems and practices to the consumer, in order to improve transparency and the social acceptability of milk, meat and eggs (Capper and Yancey, 2015). The range of improvement opportunities available indicate that the future livestock industry has the potential to be sustainable, providing that a concerted effort to improve made by all sectors within the supply chain.

Conclusion

Implementation of management practices that improve productivity, reduce resource use and GHG emissions; improve economic viability and maintain the supply of affordable milk, meat and eggs to the consumer; must be implemented with due consideration for economics, market and cultural forces. Mechanisms and programs to better educate the consumer, either directly or through retail and media channels will be essential to attempt to allow for a better understanding of livestock production and reduce the risk of animal-source foods being replaced by plant-based proteins within the human diet.

Culicoides biting midges and bluetongue virus transmission: What have we learnt since 2006?

Dr Simon Carpenter

Head of Entomology, The Pirbright Institute

Despite *Culicoides* biting midges being among the smallest blood-sucking flies, with body lengths that rarely exceed three millimeters, they are responsible for the transmission of several internationally important viruses of livestock and horses. As true flies, the developmental cycle of *Culicoides* consists of egg, four larval instars, pupa and adult and the immature stages in particular require moisture-rich habitats. The availability of these environments is therefore a key factor limiting their distribution, abundance and seasonal occurrence. Almost 1400 extant and extinct species of *Culicoides* have been described from a highly diverse range of ecosystems and the genus is present on all major land masses with the exception of Antarctica and New Zealand. Only an extremely small proportion of *Culicoides* species have a significant deleterious impact on human existence and these are generally those species that are effective in taking advantage of environmental changes implemented by agriculture. As a genus, they remain among the least studied of the major insect vector groups. This is in part a consequence of their small size and fragility, which imposes significant limitations on studies of their biology and prevents laboratory colonization of the vast majority of vector species, but is also due to the limited direct impact of *Culicoides* on human health in comparison to other vector groups (e.g. mosquitoes).

Female adult *Culicoides* act as biological vectors, meaning that there is a requirement for the viruses they transmit to infect, replicate and disseminate within them, passing from initial ingestion of blood from viraemic hosts through the gut and into the salivary glands, whereupon transmission can occur. These arboviruses (arthropod-borne viruses) are hence reliant in distribution on the presence of both species and populations of *Culicoides* that can transmit them and susceptible hosts. Globally, the most important arbovirus transmitted by *Culicoides* at present is bluetongue virus (BTV), which can replicate in all ruminants examined to date and is the aetiological agent of the haemorrhagic disease bluetongue (BT). Multiple and persistent incursions of BTV strains into Europe continue to have a huge socioeconomic impact both directly through clinical BT and indirectly through those livestock movement restrictions employed to limit BTV spread. *Culicoides* also act as vectors of African horse sickness virus (AHSV), which causes African horse sickness (AHS), a lethal disease of horses. While currently confined to Africa, AHSV remains a threat to Europe and imposes strict restrictions in the movement of horses from this region to other countries. Additional *Culicoides*-borne arboviruses of notable applied interest include Schmallenberg virus (SBV), a novel virus discovered in 2011 in Germany that causes reproductive problems in cattle and epizootic hemorrhagic disease virus (EHDV) which has a major economic impact on deer production in the USA.

During the last two decades there were significant changes in the global epidemiology of *Culicoides*-borne viruses. These were most notable in Europe, which experienced outbreaks of unprecedented severity and persistence. As a result, a disproportionate number of studies of *Culicoides* have been carried out in this region and we will mostly focus on this region in describing recent research. Following the initiation of BTV outbreaks in 1998, studies were initially based in the Mediterranean basin, but following the incursion of the incursion of the BTV serotype 8 (BTV-8) into the Netherlands during 2006 focused increasingly on North-Western Europe. We will examine how novel techniques in genetics, genomics and mathematical modeling were used by a rapidly expanding community of entomologists studying *Culicoides* to both inform responses to the virus incursions and to understand the primary drivers of transmission. We will also examine studies from outside Europe which allowed a broadening of the range of techniques used to examine the *Culicoides* genus and novel approaches devised for this genus.

The most obvious entomological response to *Culicoides*-borne arbovirus outbreaks across Europe has been the implementation of wide-scale surveys of abundance of adult midges, including identification of geographic and temporal incidence. This has been developed through wide-scale and highly intensive trapping campaigns in Italy, Spain and France in particular. Surveys use light-suction traps to record the numbers and species of *Culicoides* collected, but are prone to a wide range of biases, not least variation in how attracted species are to these baits. Nevertheless, as a relative means of monitoring abundance these traps provide a logistically straightforward solution and have proved to be very popular as research tools. The main reason for funding this surveillance is to obtain data enabling demarcation of risk of arbovirus transmission in space and time. These estimates of risk need to be sufficiently robust, however, to be of utility in drafting legislation to enable safe movement of ruminants (through identification of periods of adult vector activity) or to drive vaccination campaigns.

Data regarding species abundance is underpinned by a taxonomic framework of varying quality which is usually almost entirely focused on livestock holdings. *Culicoides* can be separated morphologically by their wing patterns and several other traits, however, overlap of characteristics and a lack of dedicated expertise has been a major barrier for research on the genus. It is known that *Culicoides* vary in their ability to act as vectors of arboviruses according to species and population, influencing the spread and persistence of these viruses. As an example, vector competence for BTV (the proportion of the population able to transmit the virus) varies at both a species and population level. Variation in vector competence is thought to determine BTV distribution in the eastern states of the USA via the presence or absence of confirmed vectors. Modeling of the spatial and temporal incidence of adult *Culicoides* has played a major role in attempts to understand the drivers underlying the changing epidemiology of BTV in Europe. The influence of climate change on the transmission of BTV has provided a major point of debate, brought into focus by influential publications that have integrated mathematical modeling, entomology and virology. At least one aspect of this debate has been settled in the form of the hypothesized recent geographic spread of vector species, but alternative regional-scale hypotheses to explain the dramatic shift in BTV epidemiology that do not invoke climate change have not arisen. In this regard, an understanding of transmission parameters for *Culicoides* to spread arboviruses might be of specific interest.

In Europe, risk of transmission for BTV, AHSV and EHDV was for several decades related directly to the presence or absence of *Culicoides imicola*, a primarily Afrotropical species which has a vast global distribution reaching from the Republic of South Africa to Spain and India. This species had been implicated convincingly in the transmission of arboviruses in both field and laboratory based studies. Naturally, following major incursions of BTV into mainland Europe from 1998 onwards, this species was the main suspect for transmission and surveys concentrated upon monitoring *Culicoides imicola*'s range in this region using light-suction trap surveys across the Mediterranean basin and southern Europe. It became increasingly obvious, however that other vector species were involved in transmission of BTV strains within areas where *Culicoides imicola* were absent, leading to concerns regarding expansion of the virus into northern Europe.

These fears were realised when BTV-8 emerged in northern Europe during 2006. In this region entomologists faced a significant problem in separating species that might be involved in transmission using their morphology and polymerase chain reaction (PCR) based methods were implemented into identification. It is notable, however that despite the huge economic impact of BTV in Europe since the late 1990's, attempts to characterize the *Culicoides* fauna within European countries have been very small scale in comparison to funds spent on wider surveillance networks. This matters due to the fact that these species of *Culicoides* are known to vary significantly in their ecology, relationships with hosts and seasonal and geographic incidence. This can have major implications

where attempts are made to model Culicoides as a single taxonomic unit and then predict biological outcomes due to the fact that multiple species with different responses are likely to be conflated in analyses. While genetic analysis studies in Europe were broadly congruent with the morphological framework used to identify possible vectors, additional species were also proposed which have not since been integrated into standard surveillance reporting.

Despite these challenges, significant progress has been made in northern Europe in linking species identification of Culicoides to their ability to transmit viruses in the field and laboratory. These studies illustrate both the importance of understanding the process of arbovirus infection in Culicoides and also the advantages that emerging technologies provide. Early attempts to implicate species in transmission of BTV-8 were plagued by the misunderstanding that detection of RNA in specimens was indicative of infection. Quantification in such studies is vital as RNA is known to persist both in Culicoides that take up virus in their blood meal but don't become infected and in those that become sub-transmissibly infected (i.e. where the virus does not disseminate to the salivary glands). Later experimentation, however, integrated robot-based technology and real-time RT-PCR into screening of field collected Culicoides for BTV RNA, enabling unprecedented speed of processing and quantification. The use of real-time RT-PCR to detect virus is also far more robust than isolation of arboviruses in not requiring a cold chain and is more easily paired with ethanol-based preservation which is used by the vast majority of collectors. Recent studies in the Netherlands directly linked disseminated SBV infections to molecular marker sequences in Culicoides. These studies are now being extended further using next generation sequencing technologies that are likely to revolutionize such studies, particularly in areas of endemic transmission. A key area that will be explored within this area is the impact of co-infection of Culicoides which may influence vector competence alongside genetic determinants.

Transmission of BTV in many other regions of the world remains poorly characterized, with either no or limited modern information available for entire regions including South America, India and China. This is largely a consequence of either the limited impact of Culicoides-borne arbovirus circulation in these regions and logistical difficulties in field-based research. With the anticipated availability of PCR-based technologies for research in this area in laboratories worldwide, studies of vector competence in Culicoides in the field and laboratory should begin to make a truly global understanding of virus: vector interactions achievable. This is important in understanding the impact of global trade on arbovirus transmission which to date is poorly understood for Culicoides-borne pathogens.

Another consequence of the development of PCR based assays has been the ability to detect blood-meal origin in Culicoides as a means of understanding what animals they prefer to feed upon. Most of the Culicoides species responsible for arbovirus transmission in Europe have been found to utilize a relatively wide range of mammalian hosts that often includes human beings. Beyond these species, there are distinct differences between Culicoides that feed on mammals and those that feed on birds that remain poorly investigated. In particular, the cues used by Culicoides to find their hosts remain largely unknown. Studies of blood-meal origin provide limited information where they are not paired with detailed descriptions of host availability and ecology in the environment (e.g. if you collect Culicoides from close proximity to cattle it may be very probable they will have fed on cattle).

True manipulative studies of Culicoides host-preference, where insects are collected on animals to define which species are feeding on them and when remain extremely rare. This is largely due to the major effort that is required to conduct them and also the fact that studies tend to be highly specific to the site and host combination used. An area that requires investigation in BTV epidemiology is Culicoides host-preference between adult cattle and sheep. There is a large amount of anecdotal evidence that cattle attract greater numbers of BTV vector Culicoides and hence may act to drive BTV transmission. Co-grazing sheep flocks with cattle

herds may have an impact in increasing or decreasing Culicoides biting rates. Culicoides host preference for individual animals, which has been characterized for Culicoides and human beings in Scotland, has also not been demonstrated for livestock. This could be approached through the use of rapidly evolving molecular markers for hosts that would allow tracing of blood-meals to a specific individual.

Another advance has been the implementation of techniques based on genomics, although these are currently only applied to colony lines of the North American vector Culicoides sonorensis. Transcriptomic analyses have already been applied to examine the areas of developmental biology in Culicoides sonorensis and aspects of innate immunity. In addition, the first full genome construction for any Culicoides has been initiated and is due for public release by The Pirbright Institute and the European Bioinformatics Institute during 2016. These studies are likely to provide a major focus for studies in the upcoming decade and a wealth of opportunities for collaboration between entomologists, geneticists and bioinformaticians. While studies at present are entirely focused on colony lines of Culicoides sonorensis, the upcoming decade is likely to see such techniques applied increasingly to other species.

Among candidate species, Culicoides imicola would be an obvious target for study as it possesses a vast geographic range and has a huge global impact as a vector of arboviruses. Methods to blood-feed Culicoides imicola have been developed that could enable genome-level analysis of vector competence. In addition, progress has been made in colonizing this species although although several aspects remain challenging. Productive colonies of Culicoides imicola would enable areas such as vector competence, immunological responses and physiological analyses to be approached more easily. They would also assist in the production of cell lines specific to this species to complement those already produced for Culicoides sonorensis. Among the other primary vectors of BTV worldwide, there are several major challenges to be overcome before the full potential of genomic techniques can be realized. For many species, including all of those acting as major vectors of BTV in Europe with the exception of Culicoides imicola, blood-feeding techniques are only poorly effective and all previous attempts at colonization have failed.

Within what is a relatively small community, a major determining factor in how successfully we implement techniques based on genetics, genomics and mathematical modeling will be in connectivity between workers. Through the almost universal use of internet-based resources by scientists, communication between veterinary workers, virologists and entomologists has advanced hugely in the past decade and demarcation between these roles have blurred in some cases. The increasing use of free-access resources will become commonplace as alternatives to traditional publishing, alongside broader data repositories. It is likely that public funding agencies will also increasingly demand public accessibility of datasets from across research areas as part of their support and this may improve the current sharing of information. This may improve the continuity of datasets which at present are fragmented across countries and regions, in part due to the way in which funding is obtained.

A reverse vaccinology approach to developing a vaccine for digital dermatitis.

Professor Stuart Carter

University of Liverpool, UK.

Digital dermatitis (DD) is a major disease of dairy cattle which presents as severely inflamed lesions on the rear feet. The lesions are extremely painful, and are associated with significant lameness making DD an important animal health concern and one of the most important infectious diseases of cattle. Thus, DD is a very important animal welfare issue which has serious economic implications for the dairy industry in the UK and worldwide. In the UK and USA, DD is considered endemic on dairy farms; it has substantial financial implications and is considered second only to mastitis as a concern for farmers. Furthermore, Bovine DD (BDD) is an important worldwide food security issue as it results in reduction in milk yield and reproductive performance. Specifically, BDD is estimated to cost a dairy holding of 65 cows \$1,517/year which equates to costing the UK dairy industry (1.85 million dairy cows) a considerable £26.4 million/year. Clearly, DD has a negative effect on UK economy where milk accounts for 16.1% of UK total agricultural output.

In recent years, DD has crossed species barriers and is now commonly reported in sheep (UK and Eire) where it is classified as a rapidly emerging disease. Furthermore, DD is increasingly found in beef cattle and is now also reported in UK goats, with very serious clinical consequences. In each species, available prevention and treatment measures fail to control DD spread and associated disease outcomes; with the disease frequently reappearing. Recently, we have highlighted the potential role of foot trimmers in disease spread.

The infectious nature of the disease is apparent and it is now widely accepted that the primary infection in each host species is the novel spirochetal bacteria. These are found in large numbers in all BDD cases, often deep within foot lesions. Molecular methods have further identified these spirochetes as *Treponema*. Cloning of bacterial 16S rRNA genes indicated 5 phylotypes of treponemes in BDD lesions from Germany. This has led to the isolation and characterisation of three of these five treponeme groups from lesions in USA and UK. Recent molecular epidemiology work at the UoL and elsewhere has identified treponemal bacteria as the common causative agents. Furthermore, an infection model recently used pure cultures of treponemes applied to the bovine host feet; the results close to fulfilling Koch's postulates to establishing a causal link between DD and treponemes.

Hence, it is imperative that a different (and preferably improved) disease management approach is needed in the near future; a vaccine that prevents the primary treponeme infection would be both ideal and timely, especially when used in conjunction with other on-farm approaches to improve hygiene and biosecurity. Such a vaccine would probably be applicable to the other known DD host species of beef cattle, sheep and goats. It may also be valuable for prevention of the many newly reported skin lesions (in several species, including pigs and horses and wild deer) associated with DD treponeme colonisation.

Prevention, control or eradication of digital dermatitis – developing a vaccine.

Whilst perfect hygiene cannot be readily achieved on dairy farms, it is clear that well managed farms have lower incidence, prevalence and severity of DD in their herds. Dairy cow DD is typically treated with footbaths of toxic compounds (such as formalin or copper sulphate) or topical antimicrobial agents which are both relatively ineffective, as lesions soon reappear. These current treatments are considered moderately effective at killing the secondary invasive bacteria, but have little effect on the deeper lying treponemes, the primary infection and thus, the disease readily recurs. Also, and very importantly, both

current treatment options are being legislated against within the EU (and potentially wider) due to either environmental risks or fear of induction of antimicrobial resistance in farmed species. Thus, prevention of disease transmission or an effective vaccine would be better options.

As the only consistent bacterial presence in DD lesions is the specifically associated treponemes, it is apparent that targeting these bacteria would be the best chance to control disease. A bacterin vaccine based on a single BDD treponeme phylogroup was initially reported to reduce the incidence of BDD but subsequent studies reported the vaccine as ineffective. As most lesions show co-infection by several BDD treponeme phylogroups, a multivalent vaccine containing cell surface proteins from several of these BDD treponeme phylogroups may finally allow for effective control of this debilitating disease. As some phylogroups of BDD treponemes are not yet cultured, identifying antigens shared by the three isolated phylotypes should allow for future vaccines to include further recombinant antigens, including proteins encoded from genes directly mined from lesions, which would bypass problems associated with growing these fastidious microbes.

Targeting treponemes to control digital dermatitis – scientific case.

Whilst DD is undoubtedly a polymicrobial disease, there is little dispute that treponemal species are the only consistent infection in all cases and that they are the probable initiating infection, with their being little evidence for consistent primary contribution of other micro-organisms.

Research, mainly at UoL, has resulted in protocols (immuno-magnetic separation/ selective media) to isolate three groups of treponemes from dairy cattle DD lesions. As a result, the UoL team now have a large treponeme isolate archive of over 100 treponemes from DD lesions as well as more than 20 from various animal tissues and, particularly, from the skin and gastrointestinal tract. Subsequently, we have generated complete genomes for representatives of these three DD-associated phylogroups as well as commensal bovine GI tract treponemes and closely related human equivalents. Collectively, this is an excellent research resource and has enabled many key developments towards a pathway for controlling this disease.

Characterisation of these spirochetes identified the isolated BDD treponemes into three groups: *Treponema medium*-like, *Treponema phagedenis*-like and *Treponema denticola*-like spirochetes, respectively, based on similarities with human oral and urinary tract treponemes as determined by 16S rRNA and flagellin gene sequencing and phenotypic characterisations. Importantly, these spirochetes, although in three distinct groupings, still cluster tightly together and are very separate from those isolated from cattle GI tract contents and from other host species and diseases. Further characterisation of the *T. denticola*-like BDD spirochetes allowed them to be designated as a new species - *Treponema pedis*. Subsequent studies demonstrated the susceptibility of BDD treponemes to a number of relevant antimicrobials with a view to potential usage in vivo. Development of PCR assays for detection of the three groups of isolated BDD treponemes then identified a high association for all three groups in UK BDD lesions. This corresponds to a recent BDD fluorescence in situ hybridisation study that identified (but did not isolate) five groups as involved in BDD aetiology, with three groups resembling treponemes isolated at UoL.

Hypothesis and approach

The central hypothesis is that by combining genomic data with novel in silico and in vitro technologies, we can identify, generate, characterise and deliver surface expressed treponemal molecules as vaccine candidates to prevent and/or control digital dermatitis in dairy cattle. If successful, the respective outcomes would enable large scale trials and potential production of a vaccine to significantly improve animal welfare, farm economics and food security.

Aims and objectives

- Using genomes and proteomics, identify surface expressed treponemal proteins which have potential as antigens and vaccine components.
- Expression, purification and reconstitution of recombinant treponeme proteins from *Escherichia coli*.
- Identify functional and virulence activities of recombinant treponeme proteins.
- Testing immunogenicity of candidate vaccine antigens in vivo
- Efficacy trials of selected treponeme proteins to test ability to prevent DD lesions developing.

Reverse vaccinology approach

Reverse vaccinology (RV) is a relatively new concept and describes the process of candidate vaccine target selection that begins with the genome of the pathogen rather than the pathogen itself. The entire genetic (and therefore antigenic) potential of the infectious agent can be scrutinised. This method permits not only the potential identification of all antigens that would otherwise have been discovered by conventional approaches, but also novel antigens not detectable or overlooked by traditional methods. In addition, reverse vaccinology is a relatively fast process (1-2 years), able to identify virtually all antigens, regardless of time of expression, abundance or immunogenicity.

Using bioinformatics approaches, the genome can be screened in silico for genes that encode proteins with antigenic potential. A computational approach to the subcellular localisation of bacterial proteins, although historically imprecise, now compares favourably to high-throughput laboratory approaches, with a wide range of bioinformatic tools freely available online for this purpose.

Genomes and bioinformatics.

From the Liverpool DD treponeme collection, genomes were generated (Roche 454 sequencing) from representatives of the 3 cultivable DD treponeme phylogroups and from commensal cattle treponemes. In silico analysis of the genomes enabled comparative genomic selection to identify genes coding for homologues of proteins likely to be surface expressed (SignalP). Once a protein's subcellular localisation is established, protein topology prediction is an important consideration during the in silico vaccine candidate selection process. Crucially, when attempting to predict prokaryote outer membrane proteins from an amino acid sequence, discrimination must be made between the integral α -helical proteins that predominate in the cytoplasmic membrane and the integral β -barrel proteins that predominate in the outer membrane. All structurally-characterised gram-negative bacterial transmembrane OMPs to date have been found to share essentially the same β -barrel topology, consisting of 8-22 anti-parallel β -barrel strands folding into a cylindrical β -barrel structure (TM-BETA, PRED-TMB). These β -barrels were prioritised in our bioinformatics search. Consequently, a large panel of putative surface expressed antigenic proteins was produced for each DD treponeme and homologs identified across phylogroups. The resulting proteins were all hypothetical and without predicted function.

Production of recombinant treponeme proteins.

Genes for selected proteins were cloned into an entry vector (pENTR), transferred into an expression vector (pDEST) and expressed in *E coli* (BL21 DE3), eventually in large scale cultures. Recombinant proteins were purified by metal affinity chromatography and refolded to native structures as assessed by SDS-PAGE and CD spectroscopy. To date 33 recombinant DD Treponeme proteins have been cloned expressed purified and successfully refolded. These have then been assessed for biofunctions such as antigenicity and evidence of virulence potential.

Antigenicity of the recombinant treponeme proteins.

Sera from cattle with and without DD lesions were screened for reactivity to recombinant treponeme proteins by ELISA and Western blotting. Many were not detected as antigenic in naturally occurring disease.

Function of recombinant treponeme proteins

Bio-assays were developed to assess the ability of recombinant treponeme proteins to bind to cattle connective tissue molecules as this would be important in pathogenesis. These highlighted those likely to attach well to host tissues and hence potential key vaccine targets.

Immunogenicity studies.

Currently, we are testing a short list of recombinant treponeme proteins (selected from the above antigenicity and bioassays) in calves to identify any generating strong immunity. Any successful proteins will then be taken forward into efficacy trials.

Conclusions

Reverse vaccinology is a very powerful tool to rapidly generate novel vaccine targets, especially for organisms for which there is little available biological data.

Acknowledgements

Many have been involved in this project. I would specifically like to highlight the contribution of colleague Dr Nick Evans at Liverpool and also the PDRA (Dr Stuart Ainsworth), PGR (Gareth Staton) and technician (Dr Jenni Mullin) funded on this project. I am happy to acknowledge considerable support from the BBSRC and Zoetis plc.

Abstract:

Helminth infections of cattle affect productivity in all classes of stock, and are amongst the most important production-limiting diseases of grazing ruminants. Over the last decade, there has been a shift in focus in the diagnosis of these infections from merely detecting presence/absence of infection towards detecting its impact on production. This has been facilitated by studies observing consistent negative correlations between helminth diagnostic test results and measures of productivity. Veterinarians are increasingly challenged to consider the economic aspects of their work, and the use of these tests should now be integrated in economic evaluation frameworks for improved decision making. In this paper, we review recent insights in the farm-specific economic impact of helminth infections on (dairy) cattle farms as well as in farmer attitudes and behaviour regarding helminth control. Combining better economic impact assessments of helminth infections together with a deeper understanding of the non-economic factors that drive a farmer's animal health decisions should result in more effective control strategies and increased farmer satisfaction.

Key words: *Cattle, helminth, diagnosis, nematode, liver fluke, helminth, economics, communication*

Introduction

Cattle are parasitized by various helminth species, the most important being gastrointestinal nematodes (GIN), lungworms and liver fluke. These pathogens can cause severe disease, affect productivity in all classes of stock, and are amongst the most important production-limiting diseases of grazing ruminants. Essentially all herds/flocks in a grass-based production system are affected. Infections with GIN and liver fluke are more chronic and the major economic impact is due to sub-clinical infections causing reduced growth, milk yield and fertility (Morgan et al., 2013). Infections with lungworm are more acute and can place a sudden high economic burden on a farm due to mortalities and sharp decreases in milk yield (Holzhauer et al., 2011). A recent comprehensive study, funded by the EU-GLOWORM project suggested an annual loss in the EU dairy cattle industry of €2.3b from GIN infections alone (P. Torgerson, personal communication).

Over the last decade, the pressure on farm income has further increased due to higher production costs and fluctuating output prices (Thornton, 2010). Subtle changes in production efficiency can make the difference between profit and loss. Efficient farming with an optimal management of inputs such as stock, feed, and labour has therefore become increasingly important. Animal health decisions have a significant impact on production efficiency, but are also subject to resource scarcity and budget constraints. Veterinarians are thus increasingly challenged to consider the economic aspects of their work for a farmer. Hence, economic evaluation frameworks are needed that can be integrated in decision making.

Once the economic value of specific animal health interventions can be demonstrated, veterinarians are faced with a second problem. How can they convince the farmer to implement their advice? Often the claim of an economic benefit will not be sufficient to induce a real change in

farm management, even if it is grounded on solid scientific evidence. In other words, we need to understand the complete rationality of farmers' behaviour in order to improve compliance with the provided advice (Garforth, 2015).

In recent years, research in these 2 fields (i.e. economics and socio-psychology) is emerging in the field of animal health in general as well as in the field of helminth control in ruminants. In this paper, we discuss the diagnostic tools and methods that are available to assess the economic impact of helminth infections on (dairy) cattle farms as well as recent insights in farmer attitudes and behaviour that can help in the development of effective communication strategies to increase the uptake of proposed intervention strategies.

Diagnosis to assess production impact

Over the last decade, an important paradigm shift occurred in the diagnosis of parasitic helminth infections in cattle. There has been a shift in focus from merely detecting presence/absence of infection towards detecting its impact on production. This is important because i) helminth infections are highly prevalent and ii) not every infection is of economic relevance. For example, fasciolosis is mostly a chronic disease, and often it is already when the infection is around on the farm. Instead of demonstrating presence of the infection, it is more relevant to identify the associated production losses to convince farmers that further diagnosis, and control measures, are worth considering (Charlier et al., 2014c). This paradigm shift has been made possible by epidemiological research that observed consistent negative correlations between helminth diagnostic test results and measures of productivity.

In first-season grazing cattle, the serum pepsinogen concentration can be used to discriminate between different levels of *Ostertagia ostertagi*-infection and morbidity and associated production losses (Dorny et al., 1999). However, the lack of standardization between laboratories and relatively high cost of the test are important constraints to its widespread uptake (Charlier et al., 2011). Faecal egg counts (FECs) of GIN correlate well with initial infection rates approximately 2 months after turnout on pasture for first-season grazing animals. However, after that period, host immunity reduces the correlation with actual worm burden and it seems impossible to indicate what weight gains are obtained by the end of the first grazing season, from FECs measured early in the season (Shaw et al., 1998). Therefore, FECs are primarily considered useful for understanding epidemiology rather than assessing infection levels or production impact (Sargison, 2013). This picture could change with new FEC techniques such as FLOTAC that detect helminth eggs in faecal samples with unprecedented sensitivity (Cringoli et al., 2010).

In adult cattle, consistent negative relationships have been demonstrated between antibody levels to GIN or liver fluke in bulk tank milk and herd-average milk production (Charlier et al., 2005; Mezo et al., 2011; Sanchez and Dohoo, 2002). In beef cattle, the quantification of antibody levels against GIN and liver fluke in meat juice obtained in the abattoir has been proposed, showing negative correlations with carcass weight and conformation score (Charlier et al., 2009). Studies have also shown negative relationships between helminth-specific antibody levels and reproduction and mortality indices at the herd level (Delafosse, 2013; Sanchez et al., 2002). Most recently, negative correlations have been established between bulk tank milk ELISA for lungworm infection and milk production. Results showed a difference in milk production and milk fat of 1.0-1.7 kg/cow per day and 0.08-0.14 % between lungworm positive and negative herds, respectively (Dank et al., 2015), providing for the first time evidence of the economic importance of subclinical lungworm infections.

These established relationships can be used to indicate helminth-induced production losses associated with a test result of a specific farm (Charlier et al., 2012). Several limitations with this approach remain, such as the lack of species-specificity of the measured antibody levels and the rather weak relationship between detected antibody levels

and production responses after anthelmintic treatment. Nonetheless, it provides an ally to communicate to farmers on the importance (or not) of a helminth infection and to help monitor potential production losses (Charlier et al., 2014b).

From production to economic impact

The impact of helminths on animal productivity is increasingly well understood (Charlier et al., 2014b), but the economic impact depends on multiple other factors such as farm-specific input and output prices and local regulations. The established links between diagnostics for different helminth infections with production losses, now allow to include this information in models that aim to assess the economic impact of the infection at regional or even farm-level. Such economic models of animal diseases are important because they contribute to balance expenditures on disease control with the actual disease costs and to evaluate the economic attractiveness of animal health interventions compared to other investment opportunities (Yalcin et al., 1999).

Considerable progress has been made in recent years with models to estimate the cost of helminth infections and/or interventions measures at the farm level. Some of these models are available to veterinarians at www.ParaCalc.com. First, there is a deterministic spread-sheet model ("cost of worm infections") where results from diagnostic methods (i.e. pepsinogen assay and serum ELISA for growing cattle and bulk tank milk ELISAs for adult cattle) to monitor the helminth infection status on a dairy herd and anthelmintic usage are used as input parameters. It produces a report with the expected annual loss due to infections with GIN and liver fluke to discuss with the farmer. The model is useful to evaluate the general importance of the infections, to monitor the evolution of costs across different years and to benchmark the results with peers. However, it does not consider the principal of "recoverable loss" (Perry and Randolph, 1999). How much of the total costs induced by helminth infections can be avoided by intervention measures? This is often difficult to determine because: (i) it is impossible to eliminate the infection from a farm; (ii) there can be remaining tissue damage after effective treatment or (iii) re-infection can occur at varying levels. Obtaining such information requires the set-up of experiments, by preference under commercial farming conditions that evaluate the impact of specific intervention measures. Such information is increasingly available, especially to evaluate the production effects of strategic anthelmintic usage (e.g. Höglund et al., 2013; Verschave et al., 2014, and this information was used to develop the second tool "treatment strategies against gastrointestinal worms" on ParaCalc.com. It estimates the likely economic benefit and uncertainty of a number of anthelmintic treatment strategies of adult cows and produces a report to discuss with the farmer.

Most recently, the farm-specific economic impact of helminth infections has also been studied using efficiency analysis (van der Voort et al., 2013). Efficiency analysis studies the conversion of input(s) into output(s) and compares the current performance level of a farm with the performance level of peer farms with similar production technologies (Coelli et al., 2005). Using this approach, GIN infections appeared to mainly constrain the efficient transformation of pasture, health related costs and labour into milk. The inefficiency related with GIN infections was reduced when higher levels of concentrates and roughage were supplied (van der Voort et al., 2014). Efficiency analysis has the potential to identify different improvement paths depending on the farm-specific production process and this was recently investigated by van der Voort et al. (2016). Farms were clustered in 3 groups depending on technical efficiency (TE) and input use. In low TE farms with a relatively low use of concentrates, there was no correlation between TE and level of exposure to GIN. Therefore, they are unlikely to improve economic performance by lowering the exposure to GIN infections. Analysis suggested they could best improve economic performance by making more use of concentrates. In farms with an intermediate TE and relatively high use of concentrates, there was a strong correlation between GIN exposure and TE. In addition, analysis showed that economic performance could

be improved by substituting part of concentrates by grazing, which could lead to a higher infection pressure. This makes monitoring GIN infection crucial in this group. In farms with the highest TE and intermediate use of concentrates, there was also a negative correlation between TE and GIN exposure. Analysis showed that economic performance could be improved by both reducing input use and reducing infection. In conclusion, efficiency analysis allows to establish links between animal disease and input use and input transformation. It can detect trade-offs and synergies between animal health interventions and input-output transformation. Whereas the implications of a vet's advice are traditionally restrained to animal health issues and the improvement of technical key performance indicators, with this technique, we should be able to place our advice better in the whole-farm economic context. This approach is still in the research phase, but it is to be expected that it will be integrated in practical decision support tools for herd health management in the medium term.

Non-economic factors that drive animal health decisions

Suppose that we have a high quality economic assessment report at hand to discuss with the farmer and that we are able to distil clear suggestions to improve his animal health management. Will this be sufficient for the farmer to implement our proposed strategies? It is now well understood that farmer's decisions about their enterprises are not solely based on financial and business criteria. Farmer's motives are rooted in deeply held values and also influenced by attitudes, beliefs and social norms (Garforth, 2015). Understanding all the values that drive farmer behaviour requires socio-psychological research, aimed to lead to increased understanding of a farmer's rationality and more effective advisory interventions (Charlier et al., 2015; Garforth, 2015).

In the field of helminth control, Vande Velde et al. (2015) investigated farmers' intention to adopt diagnostic methods before implementing anthelmintic drugs in cattle. Based on two fundamental theories in the fields of behavioural and health psychology, a survey was carried out in 574 Flemish dairy farms to investigate the influence of the following variables: 'attitude towards preventive use of anthelmintics', 'attitude towards diagnostic tools', 'subjective norms', 'behavioural control' and 'perceived risk'. The results showed that 'attitude towards diagnostic methods' and 'subjective norms'; i.e. the influence of significant others, had the strongest, positive influence on adoption intention of diagnostic methods. 'Attitude towards the preventive use of anthelmintic drugs' had a negative effect on adoption intention of the diagnostic methods. 'Perceived risk', which was defined as the perceived susceptibility and severity of anthelmintic resistance on their farm, had no effect on the intention to adopt diagnostic methods. These results implicate that if we want to persuade farmers to make more use of diagnosis before anthelmintic treatment decisions are made, we should reinforce their positive attitude towards diagnosis and make use of their social network, which could implicate family, peer-farmers and the veterinarian. At present, the argument of anthelmintic resistance has no or little effect on dairy farmers' intention to use diagnostics for helminth diseases.

In order to investigate how veterinarians can improve their communication, we can learn from socio-psychological studies that have been conducted on different topics such as biosecurity, notification of notifiable diseases, antimicrobial usage and mastitis management (Delgado et al., 2012; Hamilton et al., 2016; Jansen et al., 2009). Although the results cannot be extrapolated beyond their scope, similar patterns often emerge. Identification of different behavioural types is a first step towards more adapted advices and increased compliance. In the UK, Rehman et al. (2008) differentiated farmers with a family orientation from entrepreneurs, life-stylers, hobbyists and independent farmers, respectively. In Brazil, Pereira et al. (2016) were able to classify beef farmers that were considered receptive towards novel technology adoption based on their main sets of goals and values: the professional farmer, the committed environmentalist, the profit maximiser and the aspirant top farmer. The study showed a considerable diversity of values and goals even within

this subset of progressive farmers. This diversity should be taken into account, because the advices that are in accordance and reinforce the farmer's core values will have the highest uptake. Age may also be an important criterion as Hamilton et al. (2016) showed that young farmers (< 45 years) tend to be more entrepreneurial and amenable to change. Finally, the subjective norms, i.e. the social network surrounding the farmer, is often one of the most influential factors in driving animal health decisions (Garforth, 2015; Jones et al., 2015). This can be exploited by the organization of farmer groups to provide a forum where farmers can explore management options and learn from each other's views and experience (Vaarst et al., 2007). Group learning is most successful if it includes experiential learning, group autonomy and builds on ongoing relationships and learning opportunities (Millar, 1997). A catch can be that endemic livestock disease can be viewed as a problem for 'bad' farmers and not an issue for those individuals who manage their stock well. As such, there may be a low motivation to form groups to address what is largely perceived as an individual problem (Heffernan et al., 2008).

Conclusion

Several diagnostic tools and methods are now available to assess the economic impact of helminth infections on (dairy) cattle farms. These include herd anamnesis in combination with serum pepsinogen assay and bulk tank milk ELISA for *O. ostertagi*, *F. hepatica* and *D. viviparus*. The use of these diagnostics is being integrated in decision support tools that should allow the veterinarian to estimate the economic consequences of his interventions and advice regarding helminth control. This can contribute in general to a 'diagnosis before treat' approach and thus increase the sustainability of anthelmintic control by a more underpinned and selective treatment (Charlier et al., 2014a).

Besides economic evaluations, more emphasis will have to be put on how advices are most effectively communicated. With the current plethora in websites, blogs and other communication channels, farmers are looking for trustworthy sources where they find reliable information that is fit to their situation. Private veterinarians are widely seen as such credible sources of information (Frössling and Nöremark, 2016; Jones et al., 2015; Richens et al., 2015). Yet it appears that our communicative skills can still be improved. Farmers in general do not voluntarily communicate on their needs regarding animal health (Derks et al., 2013) and, therefore, veterinarians should actively seek those needs. Further, being more explicit during farm visits in discussing the farmer's goals and priorities and providing a clear summary at the end of the visit of any advice given, would mean a significant step forward towards improved veterinary communication (Derks et al., 2013). By understanding the core goals and values of different types of farmers, advices can be better targeted and framed in order to achieve higher compliance and farmer satisfaction.

Paratuberculosis

Michael T. Collins

Prophecy fulfilled

"The disease has, at present, a limited number of sources from which it can spread. These sources of infection will continually increase, unless agencies are operative to offset the constantly increasing commerce in cattle from such herds. ...if not controlled, it may become a more troublesome scourge for future generations than tuberculosis is for the present generation of cattle-owners." (V.S. Larson, B.A. Beach & W. Wisnicky J. Amer. Vet. Med. Assoc. 80:446, 1924).

We (veterinary medicine and animal agriculture) had our chance to deal with paratuberculosis before it became an epidemic and we muffed it. In 1900 there were only scattered reports of paratuberculosis. A 1922 Agriculture Experiment Station publication in Wisconsin fully described the disease epidemiology, pathology and methods for diagnosis. It stressed that paratuberculosis (Johne's disease) was seen in a small number of Wisconsin herds urging veterinarians and herd owners to act aggressively to eliminate the disease from infected herds and to protect those that were as yet not affected. Failure to heed these and other such warnings by veterinarians in Europe and the U.S. allowed the disease to insidiously and unrelentingly spread among herds, regions, and countries of the world.

As the famed bacteriologist Stanley Falkow once said: *"The objective of a bacterium is to become bacteria"*. The pathogen causing paratuberculosis, *Mycobacterium avium* subspecies *paratuberculosis* (*M. paratuberculosis*) has evolved very clever strategies allowing it to replicate inside macrophages, circumvent the host immune response, and persist in the environment waiting to be ingested by another susceptible host as a means of steadily increasing its numbers on the planet. Microbiologists have labeled *Mycobacterium tuberculosis* Complex (which includes *Mycobacterium bovis*), the cause of TB, the most successful pathogen on the planet. *M. paratuberculosis* is on track to one day take this title away.

Prevalence today

Today, 121 years since Heinrich Albert Johne described paratuberculosis in a Guernsey cow in Germany, well over half of all dairy herds in virtually all major dairy-producing countries are infected with *M. paratuberculosis*. The estimated herd-level true prevalence in the U.S. is now 91%. This infection, first seen in dairy cattle, has spilled over to cattle of all breeds and types. It also is prevalent in both meat and dairy goats and sheep. In the province of Ontario, Canada over half of sheep and goats herds are infected with *M. paratuberculosis*. Without question, paratuberculosis is a panzootic – and, it just might be a pandemic.

Myriad diagnosis and control tools

Scientists the world over have invested time, effort and millions of dollars toward a better understanding of the pathophysiology of paratuberculosis, its economic impacts, epidemiology, and diagnosis and control measures. Birth of the International Association for Paratuberculosis in 1988 helped foster scientific communication and collaboration. As a result, we bovine veterinarians and paratuberculosis specialists know this disease well and have numerous diagnostic tools at our disposal. We can detect cattle in the more advanced, most infectious, stage of disease using very inexpensive antibody detection tests on serum or milk samples by ELISA technology. We can detect earlier stages of infection as animals just begin fecal shedding of *M. paratuberculosis* using genetic detection assays, commonly called PCR. We have multiple culture methods for isolation of *M. paratuberculosis*, if required. We have sequenced the entire genome of *M. paratuberculosis* and can effectively discriminate among *M. paratuberculosis* strains by an array of genotyping techniques or whole genome sequencing.

We have risk assessment tools that help evaluate *M. paratuberculosis* transmission risks in herds helping to focus herd management changes on those that will limit infection spread the most. At the University of Wisconsin, we have adapted the U.S. dairy herd risk assessment tool to an iPad App facilitating on-farm completion and submission of herd risk assessments. <http://www.vetmed.wisc.edu/dms/fapm/apps.htm>. Typically, herd risk assessments reveal the need for herd owners to focus on blocking fecal-oral infection transmission to calves; a task that improves overall calf health yielding significant pay-offs beyond paratuberculosis control.

Impediments to action

Why then does paratuberculosis continue spreading? Animal trade continues unabated and is the most effective means of infection spread among herds. Barrett et al. (Vet. Rec. April, 2011) showed that the #1 risk factor for dairy herds being found infected with *M. paratuberculosis* was the direct importation of cattle (OR 19.2, p<0.001). Rarely do cattle owners expanding their herds use appropriate pre-purchase infectious disease testing, especially not for paratuberculosis. The result is an ever increasing herd-level prevalence of paratuberculosis across the globe.

Spread of paratuberculosis between countries by animal trade as they enhance their dairy industry has been repeated over and over again. China is the current best example of this. Huge numbers of cattle being imported to China as it rapidly builds a dairy industry. These cattle come from countries well-known to have a high herd-level prevalence of paratuberculosis. The result is that *M. paratuberculosis* becomes added to the list of infectious diseases that these herds must cope with; a situation that is both unfortunate and preventable. Paratuberculosis control is an added cost to production as the infected herds must invest in routine diagnostics and herd management changes to deal with the problem. Antiquated import testing regulations based on old fashioned tests applied to individual animals (rather than herds of origin) facilitate this mistake. OIE (World Organization for Animal Health) is clearly at fault for failing to promote robust international trade testing protocols thereby allowing paratuberculosis spread to continue, decades after scientists described appropriate biosecurity measures for paratuberculosis; herd-level testing with purchase of herd replacements only from herds with a high probability of being *M. paratuberculosis*-free.

At the herd level, most owners perceive that the cost of the disease, paratuberculosis, is less than the cost of the programs to control it. As a result, only those owners who see obvious clinical disease in too many cows seek veterinary help to control the infection. The majority of commercial herds (herds not selling breeding stock) see no economic motivation to test for paratuberculosis or change management practices to limit its spread.

Cattle breeders fear that a paratuberculosis diagnosis will terminate their ability to sell breeding stock and so they intentionally avoid testing for the infection. Only when they eventually sell an *M. paratuberculosis*-infected animal to another breeder do they discover that their herd is infected. Some of those owners then take this "learning opportunity" to heart, seek veterinary help, and take appropriate actions to rid their herd of the infection; yes, it can be done! Others go into denial, discounting the importance of paratuberculosis, continuing "business as usual", and thereby fostering the spread of paratuberculosis to other breeder herds whose owners are ill-informed about the importance of buying herd replacements only from test-negative herds.

Consequences

The largely uncontained global epizootic of paratuberculosis results in steadily increasing dissemination of *M. paratuberculosis* into the environment. This has consequences for both domestic animals and free-ranging wildlife. The list of wildlife found to be *M. paratuberculosis*-infected is long, and growing. Examples include; North American Bison,

deer, elk, Big Horn Sheep, Rocky Mountain Goats, raccoons and feral cats in the U.S.; fox, stoat, weasel, hare, badgers in Scotland; kangaroos and wallabies in Australia; Guanaco in Chile; and Fallow Deer in Spain. In zoos, paratuberculosis threatens multiple species of hoofed-stock and has also been diagnosed in nonhuman primates. It remains uncertain if *M. paratuberculosis* infections in wildlife are productive infections that threaten wildlife health and pose a risk for spread back to domestic species, or are simply dead-end hosts. For ruminant wildlife, *M. paratuberculosis* is definitely a health problem. Dead-end host or not, this partial list of susceptible animals highlights the capacity of *M. paratuberculosis* to jump species and the expanding impact of this pathogen on the health of all animals.

Humans apparently belong on the list of species susceptible to *M. paratuberculosis* infection. A meta-analysis by Feller et al. (Lancet Infect. Dis. 7:607, 2007) concluded that *M. paratuberculosis* is consistently associated with Crohn's disease. The most recent study by Timms et al. in Australia (PLOS ONE DOI:10.1371, February 5, 2016) is typical of most such studies. They found that 6 of 21 (29%) Crohn's patients were positive for *M. paratuberculosis* infection (PCR positive for IS900, and F57, and a 16s rRNA gene common to all mycobacteria). The organism also was successfully cultured from one of these infected Crohn's patients.

While most in the medical community continue to discount the significance of these findings, it is almost certain that humans are becoming infected and that the most probable means of infection is via the food supply. Infected dairy herds yield *M. paratuberculosis*-contaminated milk. Pasteurization is not 100% effective at killing the organism as evidenced by multiple reports of culturing viable *M. paratuberculosis* from retail dairy products. Cattle, sheep and goats with clinical signs of paratuberculosis are slaughtered and in most all cases used for human consumption. Cooking meat to a well-done condition may effectively kill *M. paratuberculosis* but most foodies would agree that this is not the ideal way to enjoy meat.

Predictions

The 1924 prediction by Larson et al. was right; paratuberculosis has become a more troublesome scourge than tuberculosis (TB), at least in most developed countries. Like bovine TB, paratuberculosis will prove to be a zoonotic disease significantly impacting both animal and human health. Given that all pathogenic mycobacteria are zoonotic, this is not a great leap of logic.

Our strategies for dealing with this panzootic/pandemic will probably not resemble the approaches taken for bovine TB control, however. Countries can no longer afford national control programs like those employed for bovine TB and animal agriculture lacks political power to convince governments to spend the huge sums of money required for such programs. But, this should not paralyze us. Instead, we should find creative ways to foster paratuberculosis control at the level of the animal, herd, region, and internationally. In search of ways to motivate producers, some will say that we need more educational programs. I disagree. We have abundant educational materials in print and on the web and our community of bovine practitioners are well-versed in paratuberculosis and able to teach their producer clients. What we need is a better business plan.

Facing the facts

Producers run businesses that must make a profit if they are to survive. Saddling them with 100% of the cost to control a disease that has health and economic implications for the entire industry, and quite probably food safety and human health, is simply not fair and will never result in real progress. What will motivate producers? The answer is simple: money. We need to put in place economic drivers coupled with industry-driven regulations that make paratuberculosis programs work without creating complex, inefficient and costly governmental programs.

Paratuberculosis can be controlled and quite possibly even eradicated. It is a fecal-oral transmitted disease just like salmonellosis and a host of other infectious diseases. Blocking transmission is simply a matter of hygiene. To insure that hygienic measures are effective it is equally important to find the infectious cows in a herd using diagnostic tests and to cull the test-positives or isolate them away from susceptible calves. None of this is "rocket science". We have herd risk assessment tools to identify necessary herd management changes. We have excellent, commercially available diagnostic tests kits available internationally. We have skilled veterinarians to coach producers in the process and insure that they stay on track. The challenge is not in what to do. Rather, the challenge is in doing those things consistently for a long time, e.g. at least 6 years for most dairy herds.

The clock is ticking and time is running out. A large-scale, multi-national clinical trial is underway that may substantiate what case reports have already shown; treatment of Crohn's disease with a cocktail of three anti-*M. paratuberculosis* antibiotics can cure a high proportion of Crohn's cases. No other therapy available today can make this claim. The ability to cure Crohn's disease using anti-*M. paratuberculosis* antibiotics may be the finding that tips the scale of scientific opinion. Consumers are concerned and Crohn's patients are increasingly aware about the potential health risks of *M. paratuberculosis* (<http://thecrohnsinfection.org/>). In addition to expecting high welfare standards for food-producing animals the public also should reasonably expect that these animals are healthy. And, animals with paratuberculosis are not healthy.

The way forward

- Veterinarians must be educators as well as guardians of animal and public health. Limiting animal and human exposure to *M. paratuberculosis* starts on the farm; the critical control point. Bovine practitioners should make paratuberculosis a part of every herd health plan.
- Dairy processors should incentivize producers to test their herds. For example, a novel program in the UK offered to pay all of the testing costs for dairy herds that were found to be 100% test-negative.
- Dairy processors should pay producers more for milk from test-negative herds; thus enhancing product safety, insuring consumer confidence, and partially compensating herd owners for their efforts to attain and sustain a test-negative herd status.
- Breed organizations should implement requirements that cattle sold by their members come from test-negative herds. By announcing such programs well in advance and phasing rules in slowly, breed organization members can collectively move toward this ideal goal. For example: organizations could first require that cattle sold only originate from test-negative dams, then require that cattle sold come from test-negative dams in herds where 30 randomly selected adults are found test-negative, and eventually mandate that cattle for breeding purposes are only sold by herds with a history of being test-negative over multiple years. Programs can begin using low-cost, low-sensitivity tests like ELISAs and eventually move toward higher cost and higher sensitivity tests like PCR on fecal samples. Naturally, veterinarians are vital for insuring the integrity of the entire process beginning with sample collection. As the Chinese proverb states: A thousand mile journey starts with one step. It's time for breeders to take that step.
- Governmental agencies should provide the infrastructure for these market-driven programs; educating veterinarians, licensing diagnostic tests, certifying laboratories and setting standards for herd classification based on likelihood of paratuberculosis-freedom. This infrastructure is already in place in many countries.
- The collective costs for paratuberculosis control will undoubtedly be passed along to consumers. There is nothing unfair about this. They will also be the ultimate beneficiaries of safer food from healthier animals.

Practical Cow-Side Laboratory Tests For The Cattle Veterinarian

Peter Constable, BVSc(Hons), MS, PhD, DACVIM, DACVN(Honorary), MRCVS

University of Illinois College of Veterinary Medicine, Urbana, IL 61802, USA; constabl@illinois.edu

Point-Of-Care Analyzers

The ready availability of point-of-care analyzers will revolutionize on farm diagnostic testing. These analyzers place patient test results immediately into the veterinarians' hands. Diagnosis is therefore facilitated, and appropriate treatment can be instituted without delay. Point-of-care analyzers have great potential to be a practice builder.

The archetypal point-of-care device is the California mastitis test (CMT). For literally a couple of cents per cow, the CMT test provides a cow-side test that provides a clinically useful estimate of the number of somatic cells in the secretion from each quarter, and therefore the likelihood of subclinical mastitis (Schalm and Noorlander, 1957). This information can be used at dry off to guide decisions related to selective dry cow antimicrobial therapy, or used as a screening test to identify cows for milk culture to identify the predominant mastitis pathogens on the dairy. A number of recent clinical examples from our laboratory will be presented demonstrating how the use of point-of care analyzers or equipment can positively impact bovine veterinary practice. Time will tell whether they impact clinical practice to a similar degree than has the CMT. The information in this presentation is additive to that provided by Professor Rollin at the 2006 World Buiatrics Congress (Rollin, 2006); Professor Rollin and his colleagues at the University of Liège in Belgium have a wonderfully equipped practice vehicle that facilitates the field diagnosis of disease and poor performance in cattle. Additional information on field chemistry analysis has also been published elsewhere (Vap and Weiser, 2007).

Glucose Meters To Identify Dairy Cows With Negative Energy Balance

Measurement of plasma glucose concentration ([gluc]) is clinically valuable in periparturient dairy cattle, particularly during the period from day 3 to day 28 of lactation. Plasma non-esterified fatty acid concentration provides the best index of energy balance in lactating dairy cows from 1 to 10 weeks postpartum (Reist et al., 2002) but its current cost (US\$9.00/test) and lack of a suitable point-of-care device prohibits routine use as a monitoring tool. Plasma [gluc] is negatively associated with energy balance in lactating dairy cows to a similar degree as serum [BHB] (Reist et al., 2002); plasma [BHB] also has a marked diurnal change based on time of feeding, whereas plasma [gluc] does not exhibit a diurnal effect (Nielsen et al., 2003). Moreover, plasma/serum [gluc] is negatively associated with plasma/serum [BHB] in dairy cattle from 2 months before to 2 months after calving (Nielsen et al., 2003; Kauppinen, 1983). Blood [gluc] can be measured for approximately US\$0.30/test whereas measurement of blood or plasma [BHB] costs US\$1.30-3.10/test; consequently, four to ten times as many cattle can have their blood [gluc] measured than their blood [BHB] for the same overall cost. This cost differential facilitates the implementation of blood [gluc] as a potentially useful index of energy balance in periparturient cattle.

The Precision Xtra® meter is a low cost electrochemical point-of-care unit for measuring blood glucose concentration ([gluc]) in cattle blood. The meter uses specialized electrochemical test strips that are screen-printed to monitor glucose and β-OH butyrate concentrations in whole blood. The first layer of the test strip contains mesh and surfactants that facilitate retention of erythrocytes and passage of plasma by capillary action to an underlying layer that employs an enzymatic reaction, with the reaction products being detected by generation of an electrical current. The meter uses an algorithm optimized for human blood that

assumes the intra-erythrocyte [gluc] equals the plasma [gluc], and that the hematocrit is similar in humans and cattle. We recently published a study with the primary objective being to determine the accuracy of the meter for measuring plasma [gluc] in dairy cattle (Megahed et al., 2015). Secondary objectives were to characterize the influence of hematocrit and sample temperature on the measured value for [gluc]. Blood and plasma samples (1,109) were obtained from 106 periparturient Holstein-Friesian cattle. Deming regression and Bland-Altman plots were used to determine the accuracy of the meter against the reference method (plasma hexokinase assay). Multivariable regression and linear regression were used to determine the effect of hematocrit and sample temperature on the plasma [gluc] measured by the meter. We found that sample temperature had a significant linear effect on plasma [gluc] as measured by the meter when the reference method [gluc] > 8.8 mmol/L. Intra-erythrocyte [gluc] was 18% of plasma [gluc] on a molar basis. We concluded that the meter utilizes an algorithm that is optimized for human blood and is inaccurate when applied to bovine blood. Until a cattle-specific algorithm is developed, we recommend using plasma as the analyte instead of blood and calculating plasma [gluc] in mg/dL using the equation: $[gluc] = 0.66 \times [gluc]_{p-meter} + 15$, where $[gluc]_{p-meter}$ is the value reported by the meter in mg/dL. If blood is measured, then we recommend using the equation: $[gluc] = 0.90 \times [gluc]_{b-meter} + 15$ where $[gluc]_{b-meter}$ is the value reported by the meter in mg/dL (Megahed et al., 2015).

B-Hydroxybutyrate Meters To Identify Dairy Cows With Hyperketonemia

Hyperketonemia is a common metabolic disorder of dairy cattle in early lactation that is characterized by increased concentrations of β-hydroxybutyrate, acetoacetate, and acetone in blood, plasma, serum, milk, and urine. Measurement of plasma or serum BHB concentration ([BHB]) is considered the gold standard test for diagnosing hyperketonemia in dairy cattle because BHB is the predominant and most stable of the three ketone bodies (Tyopponen and Kauppinen, 1980). The most commonly used cut points for diagnosing hyperketonemia in dairy cattle are plasma or serum [BHB] > 1.0-1.4 mmol/L.

The Precision Xtra® meter is a low cost electrochemical point-of-care unit for measuring blood [BHB] in cattle. Fundamental assumptions of this methodologic approach are that the measured value for [BHB] is minimally affected by changes in hematocrit and the sample temperature. Changes in hematocrit would influence the measured value for [BHB] if the intra-erythrocyte [BHB] differed from plasma [BHB], and it has been known for more than 70 years that intra-erythrocyte [BHB] is approximately one third to one half the value of plasma [BHB] in human and sheep blood (Reid, 1962). These findings strongly suggest that changes in hematocrit are likely to alter the measured value for [BHB] in cattle blood. Measurement of [BHB] in cattle blood samples at < 32°C resulted in lower measured values for [BHB] than those obtained at 37°C (Iwersen et al., 2013). The potential effect of sample temperature had not been explored in method comparison studies, where blood samples for testing are usually obtained from the finger, ear, or foot pad or by venipuncture and immediately analyzed, and consequently are assumed to be at approximately 37.0 to 38.5°C. Because the meter uses an algorithm optimized for human blood that assumes the intra-erythrocyte and plasma [BHB] are equal, and that the hematocrit is similar in humans and cattle, we were interested in characterizing the analytical performance of the meter for the measurement of blood and plasma [BHB] in dairy cattle. Secondary objectives were to characterize the influence of hematocrit and sample temperature on the plasma [BHB] measured by the meter. Accordingly, blood and plasma samples were obtained from 106 periparturient Holstein-Friesian cattle and 15 lactating Holstein-Friesian cows with experimentally-induced electrolyte and acid-base imbalances. Meter performance was evaluated using Deming regression and Bland-Altman plots. Multivariable and linear regression analysis was used to determine the effect of hematocrit and

sample temperature on the plasma [BHB]. We found that the meter was linear up to a [BHB] of 3 mmol/L as measured by the reference method. An increase in hematocrit increased the measured value for [BHB]; this result was partially explained by intra-erythrocyte [BHB] being much lower than plasma [BHB]. Changes in sample temperature caused a linear change in [BHB]meter-plasma > 3.0 mmol/L. We concluded that the meter algorithm that calculates plasma [BHB] in units of mmol/L is not accurate when applied to bovine blood. Using plasma at 37°C as the analyte instead of blood and application of the equation $[BHB]=0.54 \times [BHB]_{\text{meter-plasma}} + 0.17$ increases the accuracy of the meter. If blood is measured, we recommend using the equation: $[BHB]=0.62 \times [BHB]_{\text{meter-blood}} + 0.20$.

Portable Ion-Selective Electrode Meters For Determining Whole Blood, Plasma, Urine, Milk, and Abomasal Fluid Potassium Concentrations In Dairy Cattle

Hypokalemia is common in lactating dairy cattle with abomasal displacement or volvulus, developing in response to alkalemia secondary to sequestration of chloride in the gastrointestinal tract (Constable et al., 1991). Low feed intake, obligatory loss of potassium in milk (1.4 g of K/L of milk), hyperglycemia, and hypovolemia are also considered main predisposing factors (Constable et al., 2013). Hypokalemia is also common in lactating dairy cattle with abomasal impaction (Wittek et al., 2005) and clinical mastitis (Smith et al., 2001). Lactating dairy cattle with hepatic lipidosis and cattle receiving multiple injections of isoflupredone acetate as part of the treatment of ketosis are more susceptible to hypokalemia (Sattler and Fecteau, 2014). Development of optimal treatment protocols for hypokalemic dairy cattle requires accurate, rapid and repeated measurements of whole blood, plasma, or serum potassium concentration ($[K^+]$) because the clinical signs of hypokalemia are nonspecific and excessive potassium administration can be fatal. Two low cost ion-selective electrode (ISE) hand-held meters (CARDY C-131, LAQUAtwin B-731; Horiba, US) have recently become available for measuring the potassium concentration ($[K^+]$) in biological fluids. We were interested in characterizing the analytical performance of the ISE meters in measuring $[K^+]$ in bovine whole blood, plasma, urine, milk, and abomasal fluid. We completed 6 method comparison studies using 369 whole blood and plasma samples from 106 healthy periparturient Holstein-Friesian cows, 138 plasma samples from 27 periparturient Holstein-Friesian cows, 92 milk samples and 204 urine samples from 16 lactating Holstein-Friesian cows, and 94 abomasal fluid samples from 6 male Holstein-Friesian calves. Deming regression and Bland-Altman plots were used to characterize meter performance against reference methods. The CARDY ISE meter applied directly in plasma measured $[K^+]$ 7.3% lower than the indirect ISE reference method, consistent with the recommended adjustment of +7.5% when indirect ISE methods are used to analyze plasma. The LAQUAtwin ISE meter run in direct mode measured fat free milk $[K^+]$ 3.6% lower than the indirect ISE reference method, consistent with a herd milk protein percentage of 3.4%. The LAQUAtwin ISE meter accurately measured abomasal fluid $[K^+]$ compared to the indirect ISE reference method. The LAQUAtwin ISE meter accurately measured urine $[K^+]$ compared to the indirect ISE reference method, but the median measured value for urine $[K^+]$ was 83% of the true value measured by inductively coupled plasma-optical emission spectroscopy (ICP-OES). We concluded that the Horiba and LAQUAtwin ISE meters provide practical, low cost, rapid, accurate point-of-care instruments suitable for measuring $[K^+]$ in whole blood, plasma, milk, and abomasal fluid samples from cattle. Ion selective electrode methodology is not suitable for measuring $[K^+]$ in bovine urine.

Measuring Maternal Pelvic Area And Fetal Hoof Circumference At Parturition To Predict Dystocia

Dystocia remains a major problem in the dairy industry as it increases cow and calf mortality, decreases milk yield, delays uterine involution, and decreases reproductive performance, ultimately resulting in

substantial financial loss. Fetopelvic disproportion is the most common cause of dystocia in dairy cattle (Mee, 2008). Accurate prediction of dystocia allows early and appropriate intervention, thereby decreasing morbidity and mortality of the dam and fetus, improving animal welfare, and reducing economic losses.

We hypothesized that the measurement of calf front hoof circumference, maternal intrapelvic and selected morphologic dimensions in late gestation, and an estimate of the dam's body weight would be predictive of calving difficulty score in dairy cattle as previously documented for some of these factors in primiparous beef cattle (Short et al., 1979). We also hypothesized that the ratio of calf front hoof circumference to maternal intrapelvic area or width has clinical utility to predict dystocia in dairy cattle, as these ratios directly reflect the magnitude of fetopelvic disproportion. We investigated our hypotheses using a convenience sample of 103 late gestation Holstein-Friesian heifers and cows (Hiew et al., 2016). Intrapelvic height and width of the dam were measured using a pelvimeter and the intrapelvic area was calculated. Calf front hoof circumference and birth weight were also measured. Data were analyzed using Spearman's correlation coefficient (r_s), Mann-Whitney U test, and binary or ordered logistic regression; $P < 0.05$ was significant. Calving difficulty score (1 to 5) was greater in heifers (median, 3.0) than cows (median, 1.0). Median intrapelvic area immediately before parturition was smaller in heifers (268 cm²) than cows (332 cm²), whereas front hoof circumference and birth weight of the calf were similar in both groups. Calving difficulty score was positively associated with calf birth weight in primiparous cattle ($r_s = 0.39$) and cows ($r_s = 0.24$). Binary logistic regression using both dam and calf data indicated that the ratio of front hoof circumference of the calf to the maternal intrapelvic area provided the best predictor of dystocia (calving difficulty score = 4 or 5), with Se = 0.50 and Sp = 0.93 at the optimal cutpoint for the ratio (> 0.068 cm/cm²). We concluded that determining the ratio of calf front hoof circumference to maternal intrapelvic area has clinical utility in predicting calving difficulty score in Holstein-Friesian cattle (Hiew et al., 2016).

An Exciting Future For The Education Of Food Supply Veterinarians

Peter Constable, BVSc(Hons), MS, PhD, DACVIM, DACVN(Honorary), MRCVS

University of Illinois College of Veterinary Medicine, Urbana, IL 61802, USA; constabl@illinois.edu

We are facing a period of rapid change in Food Animal Practice. Student interest in bovine practice has declined, associated with an increase in wealth and prosperity in developed countries, an emphasis on lifestyle, and the rise in societal and economic importance of companion animals (Baumgartner, 2002; Radostits, 2003). At the same time, the development of large scale commercial cattle enterprises and globalization of agriculture have increased the demand for advanced knowledge and skills, as well as increasing societal concerns about food security and ecosystem health (Eyre et al., 2004). These changes dictate alterations in the educational process of future bovine practitioners.

The Evolution Of Bovine Veterinary Practice

There are two main models of agricultural production, the family farm and agribusiness. In simplified terms, the species is the unit of production in the family farm model and animals are frequently identified by name. In contrast, the farm is the unit of production in the agribusiness model and animals are identified by number.

The Family Farm model

The family farm model, which dominated agricultural production until the latter half of the 20th Century, consisted of numerous small diversified units of production. The nature of veterinary services provided to this community are primarily individual and emergency; the lack of high density populations meant that it was difficult to identify economically important and production limiting diseases. The diversification present on each farm also meant that the producer often lacked rudimentary health and disease knowledge. The producer therefore depended heavily on the veterinarian to provide treatment and routine husbandry procedures such as dehorning and castration. Accordingly, veterinarians and the veterinary curriculum focused on the individual "diseased" animal in the tradition of James Herriot. In the traditional family farm model, producers frequently did not participate in the treatment of sick cattle or the implementation of preventative programs, and most veterinarians maintained a time consuming individual mixed animal practice that returned a moderate income. Veterinarians also had more influence on drug use and treatment decisions.

The veterinary curriculum addressed the needs of mixed animal practitioners by providing a broad based education that was discipline based, because this was the most efficient way of transferring general veterinary medicine principles to all domestic animals. The information explosion and impressive technological advances in human medicine over the last 50 years drove large scale specialization in human medicine, with the development of numerous discipline based specialty boards. The veterinary profession in North America followed the lead of the medical profession and in the late 1960's started a system of specialization that was discipline based (Fig. 1). The demand for clinically based veterinary specialties, such as Surgery and Internal Medicine, grew as households had more disposable income and people become increasingly interested in maintaining the health and prolonging the life of their companion animals.

The Agribusiness Model

Economic pressures, sociopolitical changes, and technological advances caused a shift from the family farm to the agribusiness enterprise in

the second half of the 20th century. In essence, small scale diversified units of production were transformed into larger scale, focused units of production. Accompanying this change has been the development of four main cattle industries, dairy, beef (cow-calf), feedlot, and veal, with additional subspecialization into other areas such as contract heifer raising, bulls, artificial breeding, embryo transfer, and cloning.

The presence of high density populations meant that was easier to identify economically important production limiting cattle diseases, and to economically compare treatment and control methods. Agribusiness specialization also meant that the producer or farm manager possessed detailed health and disease knowledge relevant to their enterprise, and were less reliant on the veterinarian to provide or recommend routine treatment and husbandry procedures. In the agribusiness model, farm personnel frequently do all the routine treatment of sick cattle and implement preventative programs, with veterinarians assuming more of a consultant and trouble-shooting role (Guterbock, 2001). This has led to the widespread development of large group practices in North America, Australia, and New Zealand, with attendant subspecialization along discipline lines. The veterinary curriculum has addressed the changed landscape by adding courses on Production Medicine, Epidemiology, and more recently, Food Security.

Education Of Future Bovine Practitioners In The Professional Program

The last twenty years has seen greater worldwide interest in evaluating the effectiveness and efficiency of the educational process. The United States Department of Education has charged the American Veterinary Medical Association (AVMA) Council on Education (COE) to oversee the accreditation process for Colleges/Schools of Veterinary Medicine in the United States. The 2016 version of the COE Accreditation Policies and Procedures lists the requirements of an Accredited College of Veterinary Medicine. Section 7.11 (Standard 11) of the Accreditation Policies and Procedures (American Veterinary Medical Association, 2016) deals with outcomes assessment and states the following: "New graduates must have the basic scientific knowledge, skills, and values to provide entry-level health care, independently, at the time of graduation." The fundamental goal of defining entry-level competencies has been addressed in many countries under similar terms such as "Day one" or "Entry level" or "Year one" competencies and "Practice ready veterinarians". The World Organization for Animal Health (OIE, [Office International des Épizooties]) developed guidelines for a model core veterinary curriculum in 2012 that are offered primarily to developing and in-transition countries as an initial step to enhance and sustain national Veterinary Services (World Organization for Animal Health, 2012).

Section 7.11 of the AVMA COE Accreditation Policies and Procedures states: "The college must have processes in place whereby students are observed and assessed, with timely documentation to assure accuracy of the assessment for having attained each of the following competencies:

- 1. comprehensive patient diagnosis (problem solving skills), appropriate use of diagnostic testing, and record management
- 2. comprehensive treatment planning including patient referral when indicated
- 3. anesthesia and pain management, patient welfare
- 4. basic surgery skills and case management
- 5. basic medicine skills and case management
- 6. emergency and intensive care case management
- 7. understanding of health promotion and biosecurity, prevention and control of disease including zoonoses and principles of food safety
- 8. client communications and ethical conduct
- 9. critical analysis of new information and research findings relevant to veterinary medicine."

Defining entry level medicine, surgery, and anesthesia skills for food animal practice

The successful veterinarian needs to achieve a minimum standard in knowledge, skills, and attributes. A critical issue is defining the relevant day one medicine, surgery, and anesthesia skills for food animal practice, and developing efficient and effective methods for developing and documenting competency in these skills. Surprisingly, this fundamental requirement of defining skills has been rarely undertaken. It is vital that each country or region define the basic medicine, surgery, and anesthesia knowledge and skills related to food animal practice. Entry level knowledge, skills, and values need to be identified because most veterinary students enter clinical practice, there is limited time and resources available for lectures and laboratories in the curriculum, bovine surgery and anesthesia laboratories are expensive requiring an adequate return on investment, and societal concerns regarding the use of live animals versus non-animal alternatives. The skills should be periodically re-evaluated because of the evolving role of the bovine practitioner in response to changes in the needs of industry (fewer, larger herds, farm laborers performing some veterinary procedures), society (increased interest in animal welfare, food safety, locally sourced products), and veterinary practice (perceived change in emphasis from individual animal diagnosis and treatment to herd health and production, with post graduate sub-specialization).

The University of Illinois at Urbana-Champaign has been a pioneer in veterinary curriculum development. We investigated the basic medicine, surgery, and anesthesia skills related to food animal practice in 1998-1999 by conducting an anonymous mail survey of US veterinarians in bovine practice (Morin et al., 2002a, 2002b). To our knowledge, this was the first such survey of bovine veterinarians conducted world-wide. The response rate of 60% with 1,450 respondents was outstanding for a mail survey and clearly indicated the interest in practicing veterinarians in ensuring that colleges of veterinary medicine were producing graduates with required entry level competencies. The questionnaire asked respondents to rate the frequency and proficiency of 148 veterinary skills, including 43 surgical skills, 10 anesthesia/restraint skills, 42 individual animal diagnosis/medicine skills, 42 production medicine/herd health skills, and 11 reproduction skills. The questionnaire used 5 point Likert ratings for frequency of 0 = never, 1 = rarely (< once/month), 2 = occasionally (1-2x/month), 3 = frequently (once/week), 4 = all the time (> once/week). Frequency scores for all 148 procedures and skills ranged from 3.4 ± 0.9 to 0.1 ± 0.3; 40/148 (27%) procedures/skills and 11/53 (20%) surgical and anesthetic procedures/skills had scores > 2.0 (performed > 1x/month). These procedures and skills occurred commonly enough that they should be included in the core curriculum (didactic and laboratory). The top 10 most frequently used medicine and animal production procedures and skills (frequency score in parentheses) were injections (3.7), oral medication (3.5), pregnancy diagnosis (3.4), venipuncture (3.4), treatment of pneumonia (3.2), management of dystocia (3.0), treatment of diarrhea (3.0), auscultation of lungs (3.0), IV fluid therapy (3.0) and cardiac auscultation (2.9). Other medicine and animal production procedures and skills of interest were auscultation of the gastrointestinal tract (2.9), development of a vaccination program (2.7), development of an anthelmintic program (2.6), treatment of metritis (2.5), treatment of mastitis (2.3), rumenocentesis (1.0), ration formulation (0.9), transtracheal aspiration (0.6), cerebrospinal fluid collection (0.3), and electrocardiography (0.2) (Morin et al., 2002a).

For comparison, the top 10 most frequently used surgical and anesthetic skills were castration (3.0), epidural anesthesia (2.8), dehorning (2.7), IV or IM sedation (2.6), tattooing (2.6), treatment of foot lesions (2.5), wound management (2.4), ear implanting (2.4), flank anesthesia (2.3), and vaginal prolapse repair (2.2). The least frequently used surgical and anesthetic skills/procedures were fracture casting (1.2), joint lavage (0.7), use of surgical hyperthermia (0.7), rectovaginal fistula repair (0.7), umbilical resection (0.7), use of cryonecrosis (0.6), liver biopsy (0.4), tracheotomy/tracheostomy (0.4), tracheal intubation (0.4) and

inhalation anesthesia (0.3) (Morin et al., 2002b). As expected, there was an effect of practice type on the most common knowledge and skills. Dairy practitioners expected higher proficiency in laparotomy, surgical correction of left displaced abomasum, teat surgery, and rectovaginal fistula repair. Cow-calf (beef) practitioners expected higher proficiency in urethrotomy, urethrostomy, roping, and branding.

Similar findings to our paper were reported in a 2004 paper from the University of Missouri (Miller et al., 2004). In a 2006 paper focusing in defining the required level of competency for reproductive skills at graduation (competency score of 1 = not at all competent; competency score of 5 = extremely competent), the highest competency scores were transrectal palpation for evaluating reproductive status (3.5), dystocia management (3.4), breeding soundness exam – males (3.4), herd health management (3.3), treatment of reproductive tract disease (3.3), cesarian section (3.1), and treatment of infertility (3.0) (Kustritz et al., 2006). These findings were reinforced in a 2013 paper summarizing the skills required for food animal practice in western Canada (Luby et al., 2013). Individual animal medicine and surgery skills were performed more commonly than herd health skills. The most important skills identified were those required for physical examination, treatment of common disorders, general surgery, and basic theriogenology.

These surveys indicate that physical examination and technical skills continue to be valued more highly for entry level veterinarians than evaluative, integrative, and problem solving skills. This is a disappointing finding because it suggests that an apprenticeship model (vocational school training) may provide a more appropriate educational program for bovine practice rather than a professional program (University degree). However, bovine practice is a profession and not a trade, because in the future evaluative, integrative, and problem solving skills will be required for bovine practitioners to adequately serve and advance cattle industries.

A suitable curriculum for the future bovine practitioner

The components of the required skill set for bovine practice have been described elsewhere (Trout and Osburn, 1989; Baumgartner, 2002; Hird et al., 2002; Radostits, 2003; Kyriakis et al., 2004), but include the traditional individual animal curriculum as well as knowledge and mastery of the following components:

- Animal production systems, including agricultural economics, agricultural engineering and facility design, and globalization
- Disease control through strategic management, treatment, metaphylaxis, and vaccination
- Food security, biosecurity, and bioterrorism
- Nutrition for high production
- Population health, including evaluation using clinical epidemiology
- Public health, zoonotic disease, ecosystem health, and waste management
- Research methodology, including good clinical practice, good laboratory practice, study design, and biostatistics
- Risk assessment and risk management, including application of hazard analysis and critical control points

Additional skills needed relate to “nontechnical” or “soft” competencies, including professional characteristics related to core values and motivation, as well as suitable personality traits for supervising and motivating staff and engaging with the public (Walsh et al., 2001). Bovine practitioners will also need the skills to adapt to changing industries (Luby et al., 2013) and technologies.

Some of these modules need to be part of the veterinary curriculum for the bovine practitioner, whereas others are better situated as post graduate modules in certificate programs. It is important to recognize that the veterinary degree is not the end of the educational process, and that society demands veterinarians to be life-long learners. Implementation

of some of these modules into the veterinary curriculum will require contraction of the core curriculum and expansion of the elective curriculum (Blackwell, 2001; Eyre, 2002; Nielsen, 2003; Radostits, 2003). Whether implementation of these modules into the veterinary curriculum necessitates a move towards designated or limited licensure remains to be determined.

Students should be exposed to food animal cases in both a hospital and ambulatory setting; use of only one of these experiential programs is insufficient for day one competency in bovine practices. Although concerns regarding biosecurity at Veterinary Teaching Hospitals related to infectious disease, including Infectious Bovine Rhinotracheitis, Salmonella, Foot and Mouth Disease, and virulent strains of *Staphylococcus aureus* mastitis and *Mycoplasma bovis* mastitis are valid, experience has shown that biosecurity can be satisfactorily addressed related to cattle admissions. There is also no doubt that Veterinary Teaching Hospitals are strong and the primary vehicle for clinical education at leading Colleges of Veterinary Medicine. Ideally, the surrounding region should have a high livestock density for food and fiber animals, but this is not always possible. Having trucks that drive further afield to bring cases to and from the hospital has worked well for the Veterinary Schools in Hannover and Berlin in Germany and this approach merits wider adoption. Teaching hospitals permit more students to see great learning cases under optimal handling conditions, and provide more time for students to be involved in case management, than ambulatory or off-site experiences where time constraints are real and handling facilities may be substandard. More importantly, teaching hospitals provide veterinary students to understand disease evolution and the response to treatment, such as changes in appetite and hydration status, fecal characteristics, respiratory rate, demeanor that is not available in cross-sectional experiences in ambulatory, where animals under treatment are usually not examined each day. Hospital activities should be well integrated with discovery and engagement activity in the clinical department and relevant to the cattle industries in the region.

The main weakness with a hospital based caseload is the failure to see the animal in its environment, where the animal is part of a population. Future bovine veterinarians need to develop skills in evaluating the individual animal in the context of the population; for instance, the impact of poor building design and ventilation, poor feed quality, and inadequate nutrition on disease prevalence and severity. It is therefore important to complement the in house hospital experience with on farm experience, which could be attained using an ambulatory service, partnership with a busy food animal practice with embedded university clinicians, such as the Dairy program at the University of Melbourne in Australia (University of Melbourne Dairy program, 2016), or providing veterinary service to a large dairy farm with > 2,000 cows.

Postgraduate Education For Bovine Practitioners

Universities and Colleges of Veterinary Medicine must improve the depth and breadth of postgraduate education opportunities for veterinarians, primarily by offering learning modules and certificate programs as continuing education opportunities for veterinarians. These certificate programs could be on-site, a mixture of scheduled on-site and asynchronous distance learning programs, or entirely on-line, depending on the knowledge and skills in each module. The certificate programs would also meet postgraduate continuing education requirements in order to maintain a license to practice. Massive open online courses (MOOC's) offer one vehicle for on-line learning. The University of Illinois has been an early adopter of on-line education and a MOOC delivered in 2015 titled "Sustainable Food Production Through Livestock Health Management" provided a 6 week course of study comprising 7-9 hours/week relevant to bovine practitioners (Coursera, 2015). Students could take the course for free or receive a certificate for a fee from Coursera® indicating successful completion of the course and an acceptable result on the accompanying quizzes.

Another example of certificate programs for food animal practitioners is the Executive Veterinary Program (EVP) at the University of Illinois. Since 1991 the University of Illinois College of Veterinary Medicine has offered the EVP certificate in swine health management (University of Illinois College of Veterinary Medicine, 2016.). The program was developed to enable veterinarians to experience personal and professional development in the areas of industry trends, communication, leadership, economics and finance, marketing, legal and ethical issues, public health concerns and strategic planning. The EVP programs have been popular as they fit into their busy schedules of veterinarians being scheduled over weekends during a 12 month period, while optimizing engagement with industry leaders and providing substantial networking opportunities.

Human medicine has proceeded firmly along the path of post graduate internship and residencies, which effectively restrict the practice of medicine to specific subdisciplines. Societal needs regarding access to appropriately priced and competent veterinary services will not support the mandated requirement of internships and residencies in veterinary medicine in the absence of state provided insurance programs (such as in human medicine). Moves to lengthen the veterinary curriculum by mandating a required low paid internship year should be vigorously resisted. A more appropriate approach is to let the market place set the salary for the first year graduate based on their skill set and talents similar to Law practice; bovine practitioners that have completed modules relevant to cattle industries will command a higher starting salary than other graduates that do not have relevant focused work experiences.

There is an important role for veterinarians with graduate degrees (such as M.S., M.P.H, M.B.A, or Ph.D) in government and industry positions. There is also a role for veterinarians with specialist degrees in bovine practice, with important caveats. The discipline based system of specialization (Fig. 1) has worked well for companion animals, but has failed miserably when applied to agricultural animals. The principle reason for this failure is that most specialty boards are focused on attaining rather than applying a set of skills; agribusiness correctly places an individual animal and associated techniques as just one part of an integrated enterprise. A veterinary specialist working in the cattle industry must consider economics, practicality, animal welfare, population health, food security, ecosystem health and many other factors in every decision or recommendation.

The failure of the discipline based system to deliver an appropriately trained specialist to the cattle industry has been recognized in North America for some years. Practitioner specialty boards, which are species/industry based, were introduced in 1978. In 1997 the Surgery specialty board split into Small Animal and Large Animal components, and in 2002 the Large Animal component further split into Equine only or mixed large animal (80% Equine, 20% Food producing animals). In 2002 the Internal Medicine specialty split into Small Animal and Large Animal components and it is likely that the Large Animal Internal Medicine specialty will split into Equine and Food producing sections. These changes represent temporary patches for a failing system. Europe and Australia were late to adopt veterinary specialization and saw the failure of the discipline based approach in the US. Accordingly, European specialization can be organ, species, or discipline oriented (Lumeij and Hertzog, 2006).

Approximately half of the Colleges of Veterinary Medicine in North America align their in house clinical service units along discipline lines (such as Large Animal Medicine, Large Animal Surgery), whereas the remainder organize their in house clinical service units on species lines (such as Ruminant Medicine and Surgery, Equine Medicine and Surgery). A discipline based approach provides an inappropriate organizational structure for hospital based activities many reasons. First, clients do not request the services of Large Animal Internist, Surgeon, or Reproductive specialist, instead they request the services of a Ruminant Internist, Equine Surgeon, or Bovine Theriogenologist, depending upon their animal and the nature of the problem. Large animal clients therefore identify first with the species and industry, and then with the type of specialty. Second, the only employment opportunities for a

Large Animal specialist are located in 14 North American Colleges of Veterinary Medicine; positions for Large Animal Internists, Surgeons, or Theriogenologists or other specialists simply do not exist in private practice (although many positions exist for species-focused specialists). Third, the annual in house case is statistically and significantly lower in large hospitals organized in a discipline, rather than species, manner (Tyler et al., 2002). Finally, most large animal veterinary practitioners define themselves as multiple species (mixed) practitioners, or predominantly dairy, beef, equine, swine, or poultry practitioners. Because we should be training our professional students for a job in the real world, the organizational structure of in house activities in Clinical Science departments should reflect the real world situation and be organized along species/industry lines.

Fields of specialization should therefore first and foremost be species/industry based; for cattle industries this means that practitioners will first specialize in ruminants (or cattle), with further subspecialization in dairy, beef (cow-calf), feedlot, and veal. Under the species/industry umbrella, there is ample scope for veterinary subspecialization in a discipline-based specialty, such as Reproduction (Theriogenology), Internal Medicine, Nutrition, Food Quality and Security, Epidemiology, and Surgery (Fig. 2). This model has been adopted in Europe with the formation of the European College of Bovine Health Management in 2003 (Lumeij and Herrtage, 2006). The main objective of the College of Bovine Health Management is to advance the health and production of cattle in Europe by providing expert care for cattle; encouraging research and other contributions to the science and practice of bovine herd health management including; animal husbandry, internal medicine, surgery, obstetrics and reproductive management, as they relate to the epidemiology, pathogenesis, diagnosis, therapy, prevention, and control of diseases directly or indirectly affecting cattle.

Conclusions

Bovine practitioners must obtain skills and knowledge to adequately service cattle industries and thereby meet societal needs. This requires contraction of the core curriculum and expansion of the elective curriculum. The administrative structure of Colleges of Veterinary Medicine and particularly the Clinical Sciences departments should be organized along species/industry lines rather than discipline lines. Postgraduate specialization should also be organized along species/industry lines rather than discipline lines, with increased availability of modules or certificate programs related to areas relevant to cattle industries. Discipline based specialties (such as Internal Medicine, Surgery, Theriogenology) will become increasingly irrelevant to bovine practice unless they are placed in the context of one or more cattle industries.

A lesion oriented, life cycle approach to preventing lameness in dairy herds

Nigel B. Cook MRCVS

University of Wisconsin-Madison
School of Veterinary Medicine

Introduction

We have a global lameness crisis in our dairy industry. The worldwide prevalence of lameness in dairy herds (defined as a cow walking with noticeable weight transfer and a 'limp') is approximately 26% across studies based in Austria, Canada, China, Finland, Germany, Italy, Netherlands, New Zealand, Norway, UK and the US (e.g., Amory et al., 2006; Barker et al., 2010; Chapinal et al., 2014; Cook, 2003; Cook et al., 2016; Dippel et al., 2009; Fabian et al., 2014; Kielland et al., 2009; Popescu et al., 2014; Sarjokari et al., 2013; von Keyserlingk et al., 2012), with a trend toward lower prevalence in grazing or mixed housing and grazing systems (e.g. 16.5% in Amory et al., 2006; 8.3% in Fabian et al., 2014; and 15% in Haskell et al., 2006), and a higher prevalence in confinement housed freestall herds (e.g. 31% in Chapinal et al., 2014; 54.8% in North East US dairy herds in von Keyserlingk et al., 2013).

Despite research and a significant improvement in our understanding of the causes of lameness over the last three decades, we appear to be fighting a losing battle, and the problem has been associated with increasing intensification of the dairy industry, higher milk production and confinement housing, with the obvious conclusion that lameness is an inevitable consequence of these decisions. Consumers carry an expectation that cows should graze and appear to place considerable value on cattle having access to the outdoors, where they have fresh air and freedom to roam (Cardoso et al., 2016). They emphasize the need for humane care of the animals (Cardoso et al., 2016), so the sustainability of the industry is threatened when the general public learns that production systems do not meet their expectations – and lameness is an obvious problem that has been and should continue to be a high priority for us to resolve.

What Causes Lameness in Dairy Cattle?

The aetiopathogenesis of a variety of hoof lesions has been researched and reviewed extensively (eg. Bicalho and Oikonomou, 2013; Cook and Nordlund, 2009; Cook, 2015; Evans et al., 2015), centering on genetic, nutritional, hormonal, mechanical, infectious and environmental factors.

Across numerous surveys in different production systems, three lesions emerge consistently as the most significant contributors to lameness – digital dermatitis (DD), white line disease (WLD) and sole ulcer (SU) (eg. Barker et al., 2009; Defrain et al., 2013). Our ability to impact lameness globally will depend on developing effective control strategies targeted at these three lesions. I will concede that some differences do exist between production systems and some countries. For example, DD has yet to become a dominant hoof lesion in New Zealand and Australia, likely due to the absence of environmental risk factors. However, the disease has spread in association with confinement housed dairy systems around the world, and now even in these locations DD is appearing at a low prevalence (Chesterton, 2015). In grazing systems, WLD appears to dominate, with sole bruising and axial wall fissures often reported. It is however important to note that a healthy sole is unlikely to 'bruise' unless the sole thickness is compromised, suggesting this as an underlying cause. We know thin soles emerge as a significant problem in larger confinement dairy systems in association with toe ulceration (Shearer et al., 2006), where cows are asked to walk long distances to and from the parlor for milking. It is therefore likely that hoof wear is the underlying issue in both, due to exposure to the track (grazing herds) or concrete alley (confinement herds).

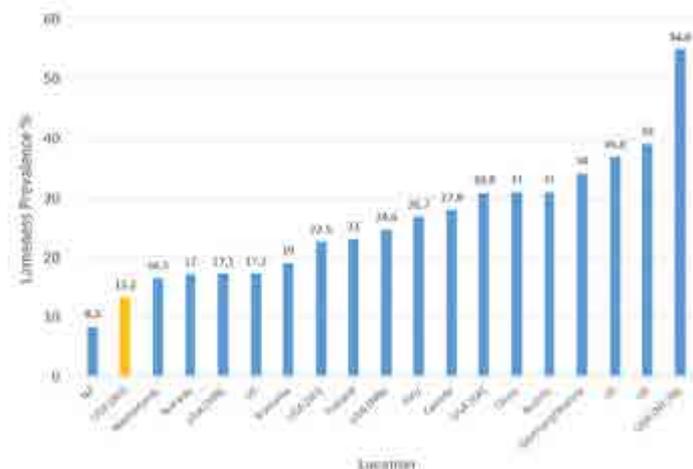

Figure 1. Worldwide prevalence of lameness in dairy herds by location from the peer reviewed literature since 2003

I will contend that we now know more than ever what causes lameness, and while we still have more to learn, we know enough currently to solve the global lameness problem in our dairy industry.

A Life Cycle Approach

No matter what the causation of lameness, once the cow develops a lesion, they are at much greater risk for developing the same lesion again in the next lactation (Oikonomou et al., 2013), likely due to permanent anatomical changes to the structure and function of the claw – including the fat pad, the suspensory apparatus and the pedal bone itself (Table 1).

Lesion	Parity	Lesion Status	Lactation Adjusted Incidence			P-value
			2	3	≥4	
WLD	1	0	6	11	15	<0.01
		1	20	21	24	
	2	0		9	13	<0.01
		1		20	18	
	3	0			10	<0.001
		1			21	
SU	1	0	12	20	26	<0.001
		1	44	32	23	
	2	0		15	24	<0.001
		1		40	30	
	3	0			18	<0.001
		1			41	
DD	1	0	7	7	8	<0.001
		1	32	15	10	
	2	0		5	7	<0.001
		1		19	12	
	3	0			5	<0.001
		1			14	

Table 1. Lactation adjusted incidence of lameness lesion (white line disease = WLD, sole ulcer = SU and digital dermatitis = DD) by lesion status (0 = no lesion, 1 = lesion) in the previous parity (1-3). (from Oikonomou et al., 2013)

We are also aware that while claw horn disease is relatively uncommon in heifers, DD infection may impact 20-30% of heifers after breeding age in many rearing facilities, likely as a result of the same poor leg hygiene risk factors that have exacerbated the problem in mature cows. Laven and Logue (2007) and Holzhauer et al. (2012) have demonstrated the importance of the pre-partum period in affecting DD occurrence during the following lactation, and Gomez et al. (2015) were able to demonstrate increased risk for DD in primiparous cows when they suffer one or more episodes of DD during the rearing period, compared to heifers that are unaffected during the rearing period.

DD affects younger cows, with incidence peaking typically in the 1st or 2nd parity, while SU and WLD incidence increases with age to around the 4th lactation (Oikonomou et al., 2013).

These data therefore support an approach to lameness control that encompasses the life-cycle of the cow, starting during the heifer rearing period, with strategies that are lesion specific and age-specific, tailored to the type of lesions that are most prevalent on each farm. Understanding the motivation for farmers to implement change is critical for consultants (Leach et al., 2010). However, it would seem likely that with the growth and expansion of welfare audits globally, they will have little choice but to comply. Ultimately, producers that have succeeded in their control of lameness will become the best salesmen of prevention programs to the others that lag behind, and these producers will increasingly need an effective roadmap to expedite change.

Herd Risk Factor Oriented Strategies

Herd level risk factors for lameness have been studied in multiple countries and in a variety of production systems in recent years. A number of consistent findings have emerged from these studies. Factors which appear to be associated with lower lameness risk include; less time standing on concrete (Bell et al., 2009), deep bedded comfortable stalls (Chapinal et al., 2013; Cook, 2003; Dippel et al., 2009; Espejo et al., 2006; Rouha-Mulleder, et al., 2009; Solano et al., 2015), access to pasture or an outside exercise lot (Chapinal et al., 2013; Hernandez-Mendo et al., 2007; Popescu et al., 2013; Rouha-Mulleder, et al., 2009), prompt recognition and treatment of lameness (Barker et al., 2010), higher body condition score (Dippel et al., 2009; Espejo et al., 2006; Randall et al., 2015), use of manure removal systems other than automatic scrapers (Barker et al., 2010), use of non-slippery, non-traumatic flooring (Barker et al., 2010; Sarjokari et al., 2013; Solano et al., 2015a), use of a divided feed barrier (rather than a post and rail system), with a wider feed alley (Sarjokari et al., 2013).

It should be expected that routine professional hoof-trimming, access to a trim-chute for treatment and use of an effective footbath program would deliver improvements in lameness (eg. Pérez-Cabal and Alenda. 2014), but these effects are often confounded in associative observational studies (eg. Amory et al., 2006). It is also true that many poorly trained hoof-trimmers cause more harm than good, and many footbath routines are ineffective through poor design and management (Cook et al., 2012; Solano et al., 2015b). Similarly, several studies point to restrictive neck rail locations, high rear curb heights, and lunge obstructions as risk factors for lameness (eg. Chapinal et al., 2013; Dippel et al., 2009; Rouha-Mulleder, et al., 2009), however correct neck rail location and curb height is stall design specific and care should be taken in interpretation of these findings.

High Production and Low Levels of Lameness

While we know that Holstein cows are perhaps more susceptible to lameness (eg. Sarjokari et al., 2013), and there appears to be a genetic component to the development of DD, SU and WLD, with a link to higher milk production (Oikonomou et al., 2013), I do not believe failure is inevitable.

We had the opportunity to visit 66 high performance Wisconsin herds that have been implementing strategies to prevent lameness for over a decade (Cook et al., 2016). These herds had a mean herd size of 851 cows, were confinement housed in freestalls and produced more than 40 kg energy corrected milk per cow per day on average. The prevalence of clinical lameness averaged 13.2% - which would rival the degree of lameness identified in grazing herds (e.g. 8.3% as reported by Fabian et al., 2014), and mixed housing and grazing or organic management systems elsewhere (e.g. 16.5% in Amory et al., 2006; 17.2% in Rutherford et al., 2008). Interestingly, it is lower than the prevalence found in similar herds in the Midwest a decade or more ago

Management Characteristic	% Herds or Mean
% Sand bedded stalls (deep loose bedding including manure solids)	62 (70)
% 2-row stall layout pens (vs 3-row)	61
% Use of headlocks at the feedbunk	83
Milking Frequency (% 3 times a day)	67
% Use of rBST	67
% Solid floor (vs slatted)	100
% Rubber floors in freestall alleys	5
% Rubber floors in transfer lanes	15
% Rubber floors in holding areas	41
% Rubber floors in parlors	68
% Manual manure cleaning from the alleys	73
% Use of fans over the resting area	96
% Use of water soakers in the pens	79
% Allow access to the outside to roam	9
% Trimming at least once per lactation	88
% Trim cows at least twice per lactation	65
% Trim heifers before calving	49
Mean footbath frequency (milkings per week)	4.5
Mean cows per full time equivalent (FTE) worker	62

Table 2. Management characteristics of the high producing multiparous group cows in elite housed dairy herds in Wisconsin (from Cook et al., 2016).

(e.g. 22.5% in Cook, 2003; 24.6% in Espejo et al., 2006), suggesting that the overall degree of lameness in the region may be improving. Severe lameness was also uncommon at a mean of 2.5%. This average is lower than that found in the majority of previous freestall surveys (e.g. 5.3% in Barker et al., 2010; 16% in Dippel et al., 2009; 4.8% in Husfeldt et al., 2012). Thus it would appear that high performance can be compatible with acceptable lameness levels, if we manage cows correctly. Table 2 highlights some of the management characteristics of these herds pertaining to lameness management.

When examining the management strategies with high levels of adoption in Table 1, there are consistencies with the herd level risk factors documented previously. These herds use deep loose bedded stalls, have 2-row pen layouts with headlocks, have solid flooring with strategic use of rubber floors, especially around the milking center. Notably, these herds were not using rubber flooring in their pens to control lameness. They clean manure from the alleys when the cows are outside the pen, and have aggressive hoof care, heat abatement and footbath programs. Two thirds of herds use rBST and milk three times daily, and perhaps surprisingly, 9% let their high producing cows outside the barn strategically – not to graze, but to spend time away from concrete floors inside the barn. In a multivariate model, deep bedded stalls, pasture access and fewer cows per FTE worker significantly reduced the risk for lameness overall.

Lameness management will continue to be refined, but these herds prove that we know enough right now to implement positive change in the dairy industry and achieve acceptably low levels of lameness, even in cattle which may be inherently more susceptible.

A Structured Approach to Lameness Prevention

When troubleshooting lameness problems, I use a structured approach starting with locomotion scoring, lesion analysis and assessment of the routine hoof-trimming and lame cow surveillance program. It is essential that the hoof-trimming is a component of prevention rather

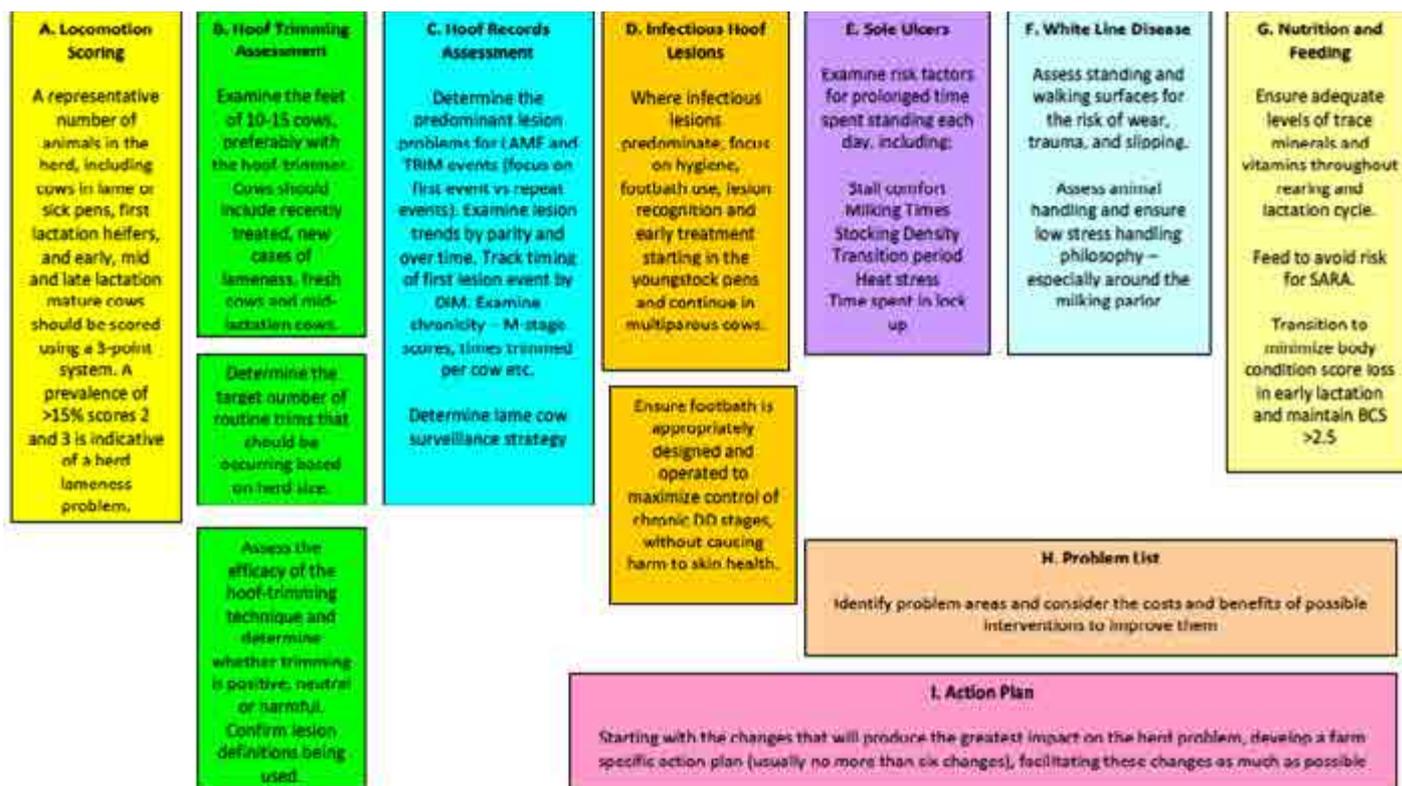

Figure 2. Herd lameness troubleshooting plan

than a risk factor in itself. I then examine the risk factors for each of the key hoof lesions and finish with a review of feeding practices. From this examination, we can create a herd specific action plan designed to maximize impact on the key hoof lesions on the farm.

For DD prevention, we focus on the early identification of acute lesions (before the cattle are lame) and prompt effective treatment, starting around breeding age in replacement heifer pens and continuing throughout the life of the animal, coupled with an effective footbath program to control the chronic lesions and hold them in check. Trace mineral supplements have a significant role to play, particularly during the rearing period. For SU prevention we target risk factors that extend daily standing times – stall design and surface cushion, stocking density, milking times, heat abatement and lock up time for management tasks. We optimize the transition period to maximize rest and reduce BCS loss in early lactation. Finally, for WLD control, we examine areas of the farm where flooring puts the cow at risk of slipping, trauma and excessive hoof wear, and watch workers to ensure low stress handling – especially around the parlor operation.

The overall approach is summarized in Figure 2. Each assessment results in a problem list which can then be used to develop a targeted action plan for the herd.

Conclusion

In this article, I have made the case, that while we still have knowledge gaps to fill in our understanding of lameness, the global crisis that we face with 1 in 4 cows walking with a painful limp can be solved by implementing our current knowledge targeted at the key hoof lesions; DD, WLD and SU. The challenge we face is one of creating a simple roadmap targeted at an individual producers most significant problems and motivating that producer to implement the changes necessary. Dairy producers that have already achieved success in lameness prevention will serve an important role motivating others to follow in their foot steps.

Introduction

Dairy herd health management is undergoing a period of radical change worldwide. The drivers of this change are many. They include the massive increase in technologies to aid in dairy cow reproductive management, quota removal (within Europe) and the significant increase in herd/farm size. Following the removal of quotas in Europe there are ambitious plans to expand dairy output, this will be achieved by a combination of increased herd size and greater milk output per cow. This paper aims to identify some of these changes and emphasise those that can facilitate enhancements in herd health and reproductive management of dairy cows.

Herd fertility and data management strategies

Historically, the emphasis in veterinary medicine has focused on the individual cow affected with a clinical disease. However, about 30 years ago it was recognized that subclinical disease was the major cause of economic losses in dairy herds. The multifactorial origin of most subclinical diseases was examined during regular herd visits by veterinarians. This turned out to be effective in improving the overall health status of the herd, and hence profitability. This approach was called herd health management and has been implemented in veterinary education for at least 3 decades. Over the same time period, Internet and Communication Technology has emerged and integrated in herd health management to leverage the understanding of cow records. The way researchers have to leverage the power of Big Data has been at the center of attention ever since the publication trend that started around 2009 (Chen et al., 2012; Sagioglu and Sinanc, 2013). How to address these challenges will be the main scope for future research.

Techniques used for analysis and visualization of traditional dairy data are not adequate for Big Data. The volume, velocity, variety, distributedness and incremental nature of such data impose challenges on the traditional methods for data analysis.

Genetic strategies to improve reproduction

Traditional dairy genetic selection programmes in dairy producing countries up to the early 2000s selected predominantly for milk yield often at the expense of other dairy relevant traits, including fertility and health. Breeding programmes in the early part of this century started to include fertility (eg longevity and calving intervals) and health as part of the selection traits. Inclusion of these traits has served to reverse some of the earlier trends that gave rise to reduced fertility. Over the last 15 years it is now recognized that trends in both longevity (increased) and calving intervals (decreased) have improved. The major challenge for breeding programmes in terms of incorporation of fertility traits has been to develop phenotypes that have high heritability. For example many fertility traits have typically only low heritability estimates (e.g., 0.1, compared with many growth and carcass traits where the heritability is 0.25-0.5). A second major issue for many fertility traits is to have easily measured phenotypic traits or genomic markers (SNPs) that correlate to appropriate fertility traits.

The EU funded project genotype plus environment has amongst its many objectives the identification of new novel milk-based phenotypes that may be used as predictors for the traditional, but difficult to measure, record and select traits such as conception rates and uterine health

(www.gpluse.eu). A key aim of the project is to develop novel milk based traits that correlate and predict health and fertility traits in dairy cows. The strategies being used include the measurement of Mid-infrared spectra (MIR), metabolites and glycans on the IgG fraction of milk. These phenotypes will be used to help identify novel genomic markers (SNPs) for fertility and health traits, this approach will allow for improved selection strategies in the future.

Furthermore recent work in University College Dublin has led to the development of glycan markers for uterine health. This has been developed into a patent application (PCT/EP2014/068734: "Methods for predicting, diagnosing or monitoring infections or conditions"). Indeed milk-based glycan markers have also been developed that can identify cows having retained placental membranes (Santoro et al., 2016). Such biomarkers that are easily measured in milk would allow animal breeders select for cows with a propensity for improved uterine health and therefore move towards cows that would have increased fertility.

Nutritional strategies to improve reproduction

Modern dairy cows have been predominantly selected for a high milk yield in early lactation that is associated with a very high capacity to mobilize body reserves during this period. Calculations showed that cows can produce as much as between 120 and 550 kg of milk per lactation from body reserves (Tamminga et al., 1997). Most cows can cope with this metabolic load that is defined as: 'the total energy burden imposed by the synthesis and secretion of milk, which may be met by mobilization of body reserves'. Metabolic stress however is defined as 'the amount of metabolic load that cannot be sustained by this mobilization, leading to the down-regulation of some energetic processes, including those that maintain general health (Knight et al., 1999). Hence, the 'over' mobilization of body reserves during the period of NEB is a key factor for disease susceptibility in modern dairy cattle.

Management strategies for transition cows are mainly focused on helping the cows to cope with the metabolic load by optimizing health, minimizing stress (e.g., by minimizing the changes in group or ration), stimulating dry matter intake and immune function. Furthermore, application of diets specifically designed to improve fertility by counteracting mechanisms related to the negative energy balance (NEB) or by supporting a specific pathway that is necessary for successful fertility, has always been a very attractive way to circumvent the impairment of reproduction during early lactation.

Controlling infectious diseases

Veterinarians managing fertility in dairy herds should regularly evaluate the herd health status for pathogens known to compromise reproductive efficiency. Infections with pathogens like *Leptospira hardjo*, Bovine Virus Diarrhoea or Herpes viruses are known to reduce conception rates, while infections with *Neospora caninum* and emerging viruses like the Bluetongue virus may cause foetal losses and abortions. Bovine Herpes Virus 4 is reported to have a tropism for endometrial cells which is therefore suggested to be especially monitored and controlled in herds suffering from uterine diseases (Donofrio et al., 2007). Besides continuing careful monitoring, appropriate biosecurity plans eventually including vaccination protocols should be implemented to prevent the introduction of new agents into the herd and to prevent eventual spread within the herd (Sanderson and Gnad, 2002).

Of special interest among infectious diseases, is the minimization of uterine diseases. In cattle, bacterial contamination of the uterus is ubiquitous at parturition. However, the latter does not automatically imply the establishment of uterine disease and subsequent fertility problems. Despite the fact that several papers have been published aiming to come to a general agreement about the definitions of postpartum uterine diseases based on mainly clinical symptoms (LeBlanc et al 2002; Sheldon et al., 2006), there is still a lot of confusion about these

definitions among practitioners. The latter gives rise to a wide variety of preventative and curative treatment protocols being applied in the field, many of which are not scientifically proven to be efficacious. Recent literature underlines the high incidence of subclinical endometritis in high yielding herds. Diagnosis of this impairment is based on intra-uterine sampling for cytology, which is not routinely done at the moment. Therefore, recently we reported the use of the cytotape that allows sampling during insemination and facilitates for example profiling in repeat breeder cows (Pascottini et al., 2015). The generally accepted necessity to minimize the use of antibiotics in cows should be extended to treatment of uterine infections. It is important to determine the risk factors for the different uterine diseases, and design prevention and control programmes to reduce the incidence of disease.

Use of precision livestock farming

Oestrous detection

Successful reproductive performance based on detection of oestrous behaviour implies the need to accurately detect oestrous onset in the majority of cows, and then inseminate 4 to 16 hours later. This led to the common practice of breeding cows according to the am-pm rule. This requires that cows are observed for oestrus 5 times per day, and those commencing oestrus in the morning get inseminated that evening and those commencing oestrus after 12.00 noon are inseminated the next morning (onset of oestrus defined as the first observation period where the cow stands to be mounted). This approach has served well for herds prepared to invest the time and effort into good and accurate oestrous detection. However, it requires a significant commitment of labour, good cow identification and personnel trained in detection of oestrus in cows.

Aids to oestrous detection

To achieve high submission rates to AI, which are critical to achieve a 365-d calving interval in seasonal calving herds, requires an effective, practical means of identifying each cow in oestrus. Both the physical activity and mounting activity induced by increased oestradiol production during the preovulatory follicular phase can be monitored in various ways. Visual observation of mounting activity for 20 min 3 to 5 times per day results in 90 to 95% submission rate (Diskin and Sreenan, 2000) but is laborious and time consuming. In high-yielding dairy cows, the percentage of cows that display standing to be mounted by other cows has decreased, leaving it more difficult to detect oestrus. Roelofs et al. (2005) found that only 58% of cows were observed in standing oestrus. This, in turn, decreases submission rate to AI and thereby contributes significantly to reduced reproductive efficiency (Diskin, 2008).

Sensors for oestrous detection

Over the last 2 decades various systems for automation of oestrous detection have been developed to various degrees of success.

Pressure sensors (Heat Watch). The characteristic oestrous behaviour of standing to be mounted can be monitored through the use of systems such as the electronic device HeatWatch, scratch cards (e.g., Estrotec; Rockway Inc., Spring Valley, WI), colour ampoules (Kamar Products Inc., Zionville, IN), vasectomized bulls fitted with a chin-ball marker, or the use of tail-painting methods (Diskin and Sreenan, 2000).

Activity monitors (eg Heat time, dairy master etc). Attempts have been made to monitor changes in physical activity to predict oestrus using automated systems. The pedometer, attached to a leg, detects an increase in the number of steps taken per hour during oestrus (e.g., S.A.E. Afikim, Kibbutz Afikim, Israel; Holman et al., 2011), whereas the use of a neck collar (e.g., Alpro; DeLaval International AB, Tumba, Sweden; Peralta et al., 2005) identifies increased physical activity (walking, mounting, getting up and lying down) expressed as an activity cluster (AC). A recent study, using the neck collar activity monitor Heatime (SCR Engineers Ltd., Netanya, Israel), identified that the odds of an AC being in a preovulatory follicular phase rather than a luteal

phase improved by 29% for every 1-unit increase in peak activity and by 91% for every 2-h increase in duration of an AC (Aungier et al., 2012). Heatime could alert the farmer as to when the AC started (when the cows next enter the milking parlour). It can identify the optimum time to AI, which is during a 12- to 18-h window before the predicted time of ovulation. This optimum time is, on average, between 9 and 15 h after the AC has been triggered (Aungier et al., 2015).

Endocrine profiling. Delaval have recently developed in-line measurement systems to detect metabolites and progesterone concentration in milk (Friggens et al., 2008). Using algorithms progesterone profiles may be de-convoluted to predict oestrous events. However, to date this technology is still relatively expensive which is limiting its adoption. In time this will likely be an important approach to managing reproduction in large dairy herds.

Oestrous synchronization and ovulation synchronization

Traditional oestrous synchronisation methods were designed to synchronise oestrus, but at best still requires observation of oestrus to optimize timing of mating and pregnancy rates. The use of 2 injection of prostaglandin 11 days apart in heifers can work well with FTAI at 72 and 96h or alternatively at 72h, and then intensively observe for oestrus for a further 3-4 days and inseminate those late coming into oestrus, in response to standing oestrus (using the am-pm rule).

Ovulation synchronisation programmes were designed to facilitate use of AI in herds without significant investment of time and labour into oestrous detection. These were developed from the early 1990s onwards (Pursley et al., 1995). They are more appropriate to large non-seasonal herds where calving to calving intervals are somewhat less relevant to economic performance of the herd and often calving intervals are allowed to extend beyond 400-420 days. The major issues for a basic OVSYNCH programme is that conception rates to a single round of OVSYNCH are approximately only 30%; and in a European context are relatively expensive. Strategies to improve pregnancy rates have been developed (e.g., Double OVSYNCH and PRESYNCH OVSYNCH; Herlihy et al., 2012) that are acceptable in many US herds, but incur substantial costs in terms of time and drug costs that leave their use questionable in European dairy herds.

Progesterone synchronization programmes can reduce the time associated with the breeding programme and are often more effective for certain categories of cows (McNally et al., 2014).

Pregnancy Detection

Direct methods of pregnancy detection

Various methods are available to determine pregnancy status, these include return to oestrus, rectal palpation of the reproductive tract and ultrasound scanning to observe the reproductive tract. In practice return to oestrus is fraught by the vagaries of oestrous observation, so currently most pregnancy detection in cows is carried out by ultrasound scanning of the reproductive tract to detect the presence or absence of the early embryo and foetal fluid. Using this method, pregnancy status is generally determined from day 28. This method while routinely used, is too late to allow rebreeding at the optimal time for non-pregnant cows.

Indirect methods for pregnancy detection in dairy cows

Indirect methods for early pregnancy diagnosis use qualitative or quantitative measures of hormones or conceptus-specific substances in maternal body fluids as indirect indicators of the presence of a viable pregnancy. Commercially available indirect methods for pregnancy diagnosis in dairy cows include milk progesterone tests and tests for pregnancy-associated glycoproteins (PAGs) in blood or milk.

Progesterone assays are reasonable as a non-pregnancy test on day 21 (Nebel, 1988). However, it is inaccurate as a test for pregnancy as

reversion to low progesterone in non-pregnant cows is highly variable due to early embryonic losses. It has been tried commercially, but has not survived due to these problems. The in-line version developed by Delaval (herd navigator) allowing repeated sampling over time has potential if the costs of repeated analyses can become competitive.

PAG measurement is a viable method of determination of pregnancy status of dairy cows (Cordoba et al, 2001), however, accuracy of PAG detection is only good after day 35 / 40. Interference may also occur due to PAG carry over from previous pregnancy for 40-50 days giving rise to a risk of false positives. It may also give false positive results after embryo loss.

Recent work from the UCD School of Veterinary Medicine has led to the development of a test based on glycan diagnostics using the IgG fraction in milk. This technology can detect pregnancy status from as early as day 16 and has led to a priority patent filing (filed 17 November 2015; UK Patent Application No.1520248.4).

The male side of the story

Although most evidence suggests the pressure on reproductive efficiency in modern dairy herds is primarily related to the high producing females, it is obvious that the role of the male should not be forgotten. While veterinary practitioners often overlook the importance of this side of the coin, farmers often blame issues like sperm quality and the expertise of the AI-technician, often because it is human nature to prefer blaming someone else instead of being critical against personal shortcomings. The success of an insemination depends amongst other factors on the deposition of appropriate numbers of sperm with a good fertilizing capacity at the appropriate site in the reproductive tract at the appropriate time in relation to ovulation. The fertility potential of an artificial insemination dose is a function of the quantity, quality, and health status of the semen contained therein. It is the task of the AI-industry to continue to maintain intense quality control programmes to ensure cryopreserved semen doses released for sale are disease free and meet the above mentioned criteria.

Therapeutics & Pharmacology

Virginia Fajt, DVM, PhD, Dipl ACVCP

Texas A&M University College of Veterinary Medicine and Biomedical Sciences, College Station, Texas, US

“Pharmacology” and “therapeutics” represent broad subjects: hundreds of books and journal articles have been published on them, even within the more limited realm of cattle pharmacology and therapeutics. By describing what I find intriguing and challenging about bovine pharmacology and therapeutics, I hope to highlight some important aspects of cattle pharmacology and to provide some food for thought about therapeutic decision-making in cattle.

Our brains work in interesting and predictably inaccurate ways, so we must compensate by being systematic in how we make therapeutic decisions.

More and more evidence suggests that our brains have two major streams: fast and slow, or intuitive and analytical, or System 1 and System 2. Experts, including all but new veterinary graduates, can be successful and accurate using the fast and intuitive system to approach diagnoses and medical management, but they can also be wrong. Being aware of the pitfalls of both types of thinking is critical to approaching therapeutic decision-making in an evidence-based and defensible manner.

How veterinarians make decision about drugs has not been extensively examined or described in the literature, but it is a fascinating aspect of therapeutics.

As veterinarians, you should aspire to justify and validate your clinical decisions, especially if your metacognitive muscles are underdeveloped. When it comes to drug decision-making, the treatment effect of a drug regimen (regimen being drug, dose, route, frequency, and duration) should be an important input as to whether and how to use drugs. It is not, however, the only input, and all the characteristics below must be balanced for adequate, accurate, and defensible drug choices. Drug choice is not always addressed as a process of clinical reasoning, so I encourage deliberate consideration of the following inputs:

“Alteration in the animal” – what has the disease or condition altered in the patient that is amenable to intervention, or what intervention in a normal animal might result in a desired physiological alteration? Are you guessing at the alteration, or do you have enough evidence to make at least a presumptive diagnosis?

“Therapeutic goal” – what is the specific desired outcome? Can it be quantified so it can be later examined to compare predicted with actual outcome to assess efficacy (see also “Indications of therapeutic success” below).

“Drug Options,” including mechanism of action and variability of response – what drugs might result in the desired therapeutic goal in the face of the particular alteration in the patient, how do they work, and how likely are they to work? No drug is effective in 100% of animals, so what is your best estimate of the treatment effect?

“Common or significant adverse effects” and “Contraindications” – are there potential adverse effects that may limit options in some animals, for example, because of co-existing conditions? Does the injection site reaction lead to significant effects on meat quality?

“Legal issues” – are there legal limitations on the drug options for the given therapeutic goal? If you are in academic practice or you mentor budding veterinarians, do you model good decision-making by weighing legal issues as or more heavily than efficacy when choosing between alternatives? Consideration should be given here also to ethical selection of drugs and regimens: even if legal, does recommending this regimen represent a conflict of interest, or would it lead to inappropriate masking

of animal conditions or behaviors, or could it result in an important public health consequence?

“Patient or Organism factors that alter regimen” – is there a characteristic of the treated animal such as disease of the organs of clearance that could alter the regimen selected? If bacterial infection is the alteration, are there resistance mechanisms present that might lead to failure or the requirement of a different dose?

“Indications of therapeutic success” – how will you know that the treatment worked? And what are your plans for monitoring outcomes to ensure that your treatment choices are as effective as you expected?

“Sources of information” – what information do you use to inform your drug decisions, and how do you acquire and critically evaluate that information?

These inputs to making drug decisions can be deliberately probed either on your own or with colleagues, exemplifying critical thinking and resulting in better decisions. Some example questions could include: Do you unintentionally limit your drug decisions by making a drug choice initially based on withdrawal time rather than efficacy? Do you always include a way of evaluating treatment outcome in your medical records? Can you defend your ultimate drug choice based on all its characteristics?

Predictions about the treatment effects and side effects of drugs are not always accurate, so scientifically valid investigations are needed to assess those predictions.

The essence of the principles of evidence-based veterinary medicine is that evidence varies in strength and quality, and we must examine both in our search for the truth about what interventions are likely to result in a measurable impact on disease outcome. Not all “Sources of information” are equal, and a systematic approach to acquiring and evaluating evidence is necessary. The general approach has been described in various ways, but the common steps are to use the knowledge gap (what do you need to know to make a decision in a particular case) to:

- Create a clinical question, with the commonest approach being the PICO-based question: patient and its problem, intervention, comparison (which may be as simple as compared to doing nothing), and outcome.
- Search for evidence to answer the question.
- Appraise the evidence for quality in terms of validity and applicability to the question.
- Apply the evidence to the question to make a decision.

There are two important outcomes of this approach: (1) a search for and review of all and of the most recent data and (2) critical appraisal of those data. By critically appraising, one determines the actual value of the data, rather than just assuming that all data are equal. Evidence pyramids have been described that attempt to weight data more heavily that come from systematic reviews of the literature or that are the result of randomized and controlled clinical trials, but the essential point is that not all data are equal. Data that are likely to be biased or for which bias cannot be assessed are of less value and should perhaps not be applied.

A third outcome of evaluating the evidence is a better characterization of the actual treatment effect associated with a drug or drugs. Treatment effect is the difference between the disease outcome with and without treatment, sometimes delineated as Number Needed to Treat or NNT. However, it can also be as simple as finding, for example, that the treatment effect of even a highly effective antibiotic on bovine respiratory disease outcomes averages approximately 50% (24% of untreated control animals vs. 71% of antibiotic treated animals, with an outcome of recovery rate). Predicting drug efficacy in this way is much different than what might be a more common, at least to the novice, notion that untreated animals never recovery and treated ones always do (100% recovery rate)!

But what if a systematic review of the literature or knowledge summary does not exist, or what if there are no in vivo or even in vitro data available? Clinical experience is often touted as the next best source of evidence. Veterinarians must be aware, however, that using clinical experience inevitably brings bias to the table, with the most common errors being a result of a lack of a comparison group, confounding by indication, loss to follow-up, and biased outcome measurements.

Cattle are food animals, so the disposition and effects of drugs in cattle in terms of food safety and food quality are important inputs to therapeutic decision-making.

As mentioned above in the "Legal issues" input in drug decision-making, cattle veterinarians know that they have important responsibilities in keeping food products from cattle safe from harmful concentrations of drugs (or withholding animals treated with dangerous drugs from the food supply). This may be as simple as following the labeled withdrawal time for a particular product, but it may be as complicated as extrapolating a withdrawal time from the scientific literature or having a difficult conversation about the ethics of a particular drug and regimen. Other considerations globally related to the importance of food safety considerations include the veterinarian's responsibility in understanding access to drugs, the drug approval process in your jurisdiction, your assurance of drug safety and purity (particularly of importance for drug compounded from bulk active pharmaceutical ingredient), and so on.

In addition to food safety, veterinarians can play an important role in contributing to food quality, for example, in the selection of drug products that are less irritating or that can be administered in areas of the animal that are of lower economic value. Beef Quality Assurance programs include best practices on injection sites because of the potential impact on tenderness, and veterinarians can lead the way in making therapeutic choices that are likely to be effective AND to result in a high quality food product.

Science does not always trump politics.

Even when veterinarians use evidence and systematic decision-making processes, other factors can intervene in treatment decisions, because bovine veterinarians today are at the intersection of science and politics. Salient examples include (1) the impact of use of antibiotics in animals on the global public health crisis of increasing antibiotic resistance, (2) animal management practices and procedures that result in pain or affect animal welfare, and (3) the potential for conflict in the desire to feed growing populations by maintaining or creating sustainable food production while minimizing environmental impacts (e.g., climate change, bacterial or chemical contamination) in the face of uncertainties in the currently available data and in the ability to predict the trajectory of any of the inputs or outcomes. It is fair to say that all of these examples could be addressed to some degree by analyzing the available scientific data. However, the scientific data may not be unequivocal in its ability to provide evidence-based recommendations for future behavior given the complicated and broad nature of these issues. More importantly, even well-designed unambiguous data about antibiotic resistance, animal welfare and pain, and sustainable food production may not be persuasive given the underlying moral facets of these topics. And moral arguments often lead to political action.

So what should the bovine veterinarian do? In my experience, advocacy whether local, regional, national, or international can have an impact, as can engagement in veterinary professional organizations. Importantly, veterinarians must not lose heart. Fringe opinions may get the attention, but often the people actually doing the work of governing and regulating are trying to listen to the scientists and the health professionals. And when health professionals disagree, best practices in conflict resolution and mediation can result in closer alignment in solving the problem.

Overview of Metabolic Disease: Impact of Energy, Protein and Mineral Issues on health and immunity of the periparturient cow

Jesse P. Goff

Iowa State University, Ames, IA

Most of the metabolic diseases of dairy cows—milk fever, ketosis, retained placenta, metritis, and displacement of the abomasum—occur within the first 2 wk of lactation. The etiology of many of these metabolic diseases can be traced back to problems in three basic areas. These are energy and protein balance, hypocalcemia, and immune dysfunction. The incidence of both metabolic and infectious diseases is greatly increased whenever one or more of these physiological functions are impaired.

Energy considerations for periparturient cows

The optimal energy content of the diet fed to the cow prior to calving is a controversial topic. The trend for many years was to feed the cow a diet with a higher energy concentration than she requires for most of the dry period. The rationale for this strategy included: 1. Adaptation of rumen microbes (Huntington, et al., 1981) and rumen papillae (Dirksen and Liebich, 1985) to the type of high-energy diet the cow will receive in lactation; 2. Maximizing DMI prior to calving as this may be correlated to DMI in early lactation (Grummer, 1995); and, 3. A diet with higher energy concentration can compensate for the decline in dry matter intake commonly observed in the final week of gestation. This might prevent the cow from going into negative energy balance just before calving. Unfortunately, this strategy is based on the premise that the dry matter intake depression just before calving would be similar in cows fed low and high energy diets during the final weeks of gestation, which may not be true (Beever, 2006, Grummer, 2008).

Increasing the non-fiber carbohydrate content of a pre-partum ration will often increase DMI across the entire three weeks of the close-up period (Holcomb, et al., 2001, Minor, et al., 1998). Increasing the energy content of the pre-partum diet has also been reported in some studies to result in lower blood non-esterified fatty acid (NEFA) or β -hydroxybutyrate (BHBA) concentrations and lower liver triglyceride accumulation (Doepel, et al., 2002, Mashek and Beede, 2000, Vandehaar, et al., 1999). However, this approach does not generally result in increased DMI after calving or increased milk production. There is also indirect evidence that supplying energy to the cow in excess of her needs may render her tissues less sensitive to insulin (Holtenius, et al., 2003; Dann, et al., 2006). Displacement of the abomasum is also promoted whenever the NFC content of the diet is increased, unless great care is taken to maintain physically effective fiber content of the ration (Coppock, 1974). When higher energy diets are fed more than 5-6 weeks prior to calving the cows may also gain excess body condition. Data also suggest increasing energy density of pre-partum diets actually leads to a greater decline of DM and energy intake in the 2-4 days before calving, i.e. the number of kg/d by which DMI is depressed just before calving may be greater in cows on the higher energy diets (Hayirli, et al., 2002, Ingvarsen and Andersen, 2000, Minor, et al., 1998, Olsson, et al., 1998)

Retrospective evidence suggests those cows suffering a bigger change (# kg) in DMI just before calving will be at greater risk of energy related disease (Grummer, et al., 2004). Studies on periparturient immune function also suggest those cows suffering the greatest decline in feed intake just before calving are most immune suppressed, leading to increased incidence of metritis and endometritis (Hammon, et al., 2006, Urton, et al., 2005). If DMI during the week before and after calving is critical to avoidance of fatty liver-ketosis and improved immune function—how do we best feed the cow to achieve this?

In the last ten years a number of dairies have adopted the strategy to

shifted to feed a lower energy diet, which utilizes straw or mature hay as a major component of the diet. Typical steam-up diets often provide ~ 1.56 Mcal NE_L / kg. The lower energy diets typically provide about 1.35 Mcal NE_L / kg diet. It should be noted that the typical DM intake of the low energy diets across the three weeks before calving will be 1-2 kg / day lower than with the high energy, higher starch diets. However, it must be emphasized that the low energy diets still provide more energy to the cow than she requires. The High energy diets provide 4-6 Mcal / day more than the cow requires. This seems to reduce their desire to eat the last days of gestation and first days of lactation. The high straw diets do provide another major advantage— a lower incidence of displaced abomasum is observed in herds fed these diets. Studies have been less successful in demonstrating these diets improve milk production or reduce the incidence of ketosis and other disorders. Perhaps it is time to focus more on the fresh cow diet as a cause of many of the fresh cow's energy problems?

Negative Protein Balance in Fresh Cows

The fresh cow is also in negative protein balance shortly after calving. The typical cow will lose 16 kg body protein during the first 2 weeks of lactation. Much of this body protein is being used to support the amino acid and glucose requirements of milk production (Paquay et al., 1972). Therefore in many respects the dairy cow in early lactation is in a physiological state comparable to that of humans and rodents with prolonged protein-calorie restriction. Glutamine is the most abundant free amino acid in human muscle and plasma and is utilized at high rates by rapidly dividing cells, including leucocytes, to provide energy and optimal conditions for nucleotide biosynthesis. As such, it is considered to be essential for proper immune function. Interestingly, plasma glutamine does not seem to be depressed in the dairy cow at calving – when body fat mobilization is rapidly increasing and presumably protein catabolism would also be increasing rapidly. However plasma glutamine does decrease as the cow progresses into the early weeks of lactation (Zhu et al., 2000, Meijer et al., 1995). Cows are in negative protein balance for 1-2 weeks after calving. Meijer et al., 1995 found that plasma levels of many of the essential amino acids fell drastically after calving and took about 10 days to 2 weeks to return to baseline levels. Plasma concentrations of glutamine, the non-essential amino acid used as an alternative energy source by many cells, including immune cells, did not return to normal levels until the cows returned to positive energy balance some 3-5 weeks into lactation.

Does the relative calorie-protein deficiency of the early lactation cow impact her immune response? In humans, protein-calorie restriction has severe effects on cell-mediated immunity. There is often widespread atrophy of lymphoid tissues and this can cause a 50% decline in the number of circulating T-cells. Surprisingly antibody responses are intact and phagocytosis of bacteria is relatively normal. However destruction of bacteria within the phagocytes is impaired (Roitt, 1991). Moderate calorie restriction (with or without a severe reduction in fat intake) has been used to ameliorate the effects of auto-immune disease, presumably by reducing cell-mediated immune responses (Leiba et al., 2001).

In mice, malnutrition leads to immune dysfunction with greatly increased morbidity. Mice fed protein deficient diets and experimentally infected with parasites had worm burdens that were significantly higher than in mice fed adequate protein (Boulay et al., 1998). C57Bl/6 mice fed a low-calorie diet demonstrated a marked reduction in T-dependent-antigen-specific lymphocyte proliferation and antibody response when compared to mice fed ad libitum. The depressed lymphocyte response seen in calorie-restricted animals is attributed to a defect in both the macrophages and T cells in antigen processing, presentation, and/or proliferation (Christadoss et al., 1984).

We know very little about the effect protein/energy restriction might have on bovine immune function. One small study examined the effect of protein/energy restriction for 133 days on nine cows infected

with tuberculosis. Dietary restriction did not result in any significant reduction in skin sensitivity to PPD, in vitro production of IFN-gamma, or lymphocyte blastogenesis. The number of circulating BoCD4+ cells and B cells were similar in both the malnourished and the control cattle. However, significantly lower numbers ($P < 0.01$) of circulating BoCD2+ cells, BoCD8+ cells, WC1+ gamma delta T cells and ACT2+ cells were found in the malnourished cattle (Doherty et al., 1996).

Management factors that will greatly influence the degree of negative energy and protein balance a cow will experience include number of cows in a pen (overcrowding), bunk space (optimal is 30 inches / close-up cow and perhaps also in fresh cow pen), number of "beds" for cows, movement of cows in and out of pens, timing of movement and number of moves in the transition period.

What is the energy cost to mount an immune response?

Little to no work has been done to examine this issue in cattle. However, in humans suffering from severe infection causing sepsis (various degrees of fever, increased WBC count, and acute phase protein production), the resting energy expenditure (determined by indirect calorimetry), increased progressively over the first week of the infection to around 40% above normal and was still elevated 3 weeks from the onset of illness. As an aside; over a 3-week period patients lost 13% of their total body protein (Plank and Hill, 2000).

No such measurements have been reported for cattle. However if we are allowed to extrapolate and speculate we can go through a few calculations. Maintenance energy for a 600 kg dairy cow is approximately 9.7 Mcal Net energy / day. If the cow must also increase energy expenditure 40% to mount an inflammatory response the energy requirement increases by nearly 4 Mcal / day. This is roughly equivalent to a requirement that the cow consume an additional 2.4 kg of diet (assuming a diet that provided 1.65 Mcal NEI/kg). Can the periparturient cow, already in negative energy balance, be expected to successfully mount a rapid immune response? If she is in fact in negative protein balance as well, will her immune system produce the immunoglobulins and acute phase proteins necessary to fight an infection while it is still in the initial phases to prevent it from escalating to a severe clinical infection?

Hypocalcemia – impact on cow health

Total blood Ca concentration in the adult cow is maintained between 8.5 and 10 mg/dL (2.1 and 2.5 mmol/L). Nearly all cows will experience some degree of hypocalcemia at the onset of lactation- the severity and duration of the hypocalcemia experienced depends on the integrity of the cow's Ca homeostasis mechanisms. Typically, the nadir in blood Ca concentration occurs 12- 24 h after calving. Surveys in the USA suggest around 5% of cows will develop milk fever each year, and the incidence of subclinical hypocalcemia – blood Ca values between 8 and 5.5 mg/dL (2 and 1.38 mmol/L) during the periparturient period – is around 50% in older cows (Reinhardt et al., 2011). Cows with sub-clinical hypocalcemia mobilize more body fat resulting in higher blood Non-esterified fatty acid (NEFA) concentrations, increasing the risk for ketosis and displaced abomasum. Hypocalcemia reduces rumen and abomasal motility increasing the risk of abomasal displacement. Hypocalcemia also reduces contraction of the teat sphincter muscle responsible for closure of the teat orifice after milking, thus increasing the risk of mastitis. Hypocalcemia is accompanied by reductions in intracellular endoplasmic reticulum and mitochondria stores of Ca in blood mononuclear cells. This impairs immune cell response by reducing the release of the "second messenger" Ca into the cytosol from intracellular stores in response to an activating stimulus (Kimura et al., 2006). Martinez et al., (2012) found that sub-clinical hypocalcemia impaired many aspects of neutrophil function and cows with sub-clinical hypocalcemia had higher blood b-hydroxybutyrate concentrations than normocalcemic cows. They also

concluded the relative risk of developing metritis increased by 22% for every 1 mg/dL decrease in serum Ca below 8.59 mg/dL. Sub-clinical hypocalcemia increases the risk for fatty liver development and reduces fertility of the cow (Chamberlin et al, 2013). Milk fever and subclinical milk fever should be considered gateway diseases that greatly reduce the chance for full productivity of a cow in the ensuing lactation.

Why does calcium homeostasis fail in some cows?

In most cows, the sudden exodus of Ca from the blood to support milk production is successfully met by reducing urine Ca excretion, increasing removal of Ca from bone fluid and bone crystals, and extraction of Ca from the diet- by both passive and vitamin D dependent transport mechanisms.

At one time it was thought milk fever occurred as a result of failure of the parathyroid glands to recognize and respond to the hypocalcemia induced by the onset of lactation. However, it was later discovered that cows developing milk fever have very high concentrations of PTH in their blood. In a landmark study, Martig and Mayer (1973) were able to demonstrate that the response of late gestation cows to exogenous PTH (which should cause an increase in blood Ca concentration) was diminished compared to the response elicited by PTH administered to cows in lactation, but they were not able to discern the cause. In severe cases of "relapsing" milk fever (cows relapsing and becoming recumbent again some hrs after the typical intravenous calcium treatment), it was observed that the secreted PTH in these cows fails to stimulate production of 1,25(OH)₂D to the same extent it does in cows with less severe milk fever (cows that require only a single intravenous calcium treatment to effect a recovery). This again suggested the periparturient cow's tissues were temporarily refractory to PTH stimulation (Goff et al., 1989). Experimental studies have identified a number of factors that interfere with Ca homeostasis in the cow. These factors are discussed below along with measures that can be taken to overcome their effects.

HIGH DIET CATION-ANION DIFFERENCE

Elegant work by Norwegian researchers Ender and Dishington in the 1970's demonstrated reducing the dietary cation-anion difference (DCAD), defined as the difference in the number of milliequivalents of cations (primarily K and Na) and anions (primarily Cl and S) in the pre-calving diet, improved Ca homeostasis at the onset of lactation. Block (1984) was able to confirm and extend this observation. Goff and Horst (1997) demonstrated high dietary K induced a metabolic alkalosis and found the risk of developing severe periparturient hypocalcemia was greatest in those cows in a state of metabolic alkalosis. Similar results were observed when Na was added to the prepartum diet. A recent study fed late gestation cows a High DCAD, alkalinizing diet or a Low DCAD, acidifying diet and treated the cows with synthetic exogenous PTH. The cows fed the alkalinizing diet had a greatly diminished response to the PTH compared to cows fed the acidifying diet. Their kidneys did not produce as much 1,25(OH)₂D and serum Ca did not rise as quickly (Goff et al., 2014). The authors speculate the tertiary structure of the PTH receptor is altered during metabolic alkalosis, reducing its affinity for PTH and resulting in a state of pseudohypoparathyroidism (Figure 2B). In many cows, despite the fact that bone and kidney cells are exposed to very high concentrations of PTH at the onset of lactation, they respond only poorly to the PTH. Addition of anions to a diet to counteract cations in the diet of a cow reduces the alkalinity of the blood and restores tissue responsiveness to PTH at the onset of lactation. Most studies have found physiological functions stimulated by PTH, such as osteoclastic bone resorption and production of 1,25(OH)₂D, were enhanced in cows fed diets with added anions. However, not all studies demonstrate an increase in osteoclast activity when cows are fed anionic diets.

Bovine Tuberculosis Eradication in Ireland

Margaret Good and Anthony Duignan

Department of Agriculture & Food, Kildare St., Dublin 2

The Irish bovine tuberculosis (bTB) eradication programme, driven by production losses in cattle, human health problems and a desire to trade in live bovine animals, commenced in 1950 and by 1962 was compulsory nationwide. The programme ensures that production losses in cattle and human health concerns are no longer an active issue, and that Ireland may avail of trading opportunities, which expanded post 1965, as European trading conditions for live animals were met. Unlike in those countries, which have succeeded in eradicating bTB Ireland has a wildlife species (*Meles meles*), in which TB is endemic, sharing the same environment as bovines. Considerable research effort has been devoted to determining the contribution of wildlife to the Irish bTB problem and in developing a viable long-term solution. Ireland has set a goal of bTB eradication in 2030 and intends with strict adherence to testing, controls and biosecurity, together with continued measures to address wildlife TB to achieve that target.

Introduction

An account of the success of the bTB eradication programme in Ireland was written fifteen years after its commencement. Fifty years later we look again at progress made.

Losses due to overt disease in cattle, human health problems caused by *M. bovis* and trading requirements, with the British seeking attested store cattle from Ireland, led to the decision to commence the Irish bTB eradication programme. A bTB scheme had commenced in Britain in 1935. British research and experience in the conduct of the tuberculin test informed the Irish programme.

In 1964 Directive 64/432/EEC, the 'trading' Directive governing trade in live bovine animals within, between and to Member States of the European Economic Community had been adopted. By 1965 Ireland, although not in the EEC, had no herds of unknown disease status and on at least one occasion during the previous 11 years, all Irish herds either had individually achieved Officially Tuberculosis Free (OTF) status or been designated infected thus fulfilling the primary conditions to allow Ireland to take advantage of possible trading opportunities opening up within Europe. The downward trend in bTB was expected to continue towards final eradication. Instead, the eradication programme stalled with ~30,000 animals failing the tuberculin test and being removed annually (Figure 2). The veterinary dispute in 1975/76 and again in early 1985 curtailed the testing programme while ongoing, but seemed to have no lasting impact.

In 1975 Leslie and others highlighted that bovine tuberculin PPD¹ had both sensitivity and specificity advantages over human PPD and thus bovine tuberculin was used from 1976. In 1980 tuberculin potency issues resulted in change in the supplier. In 1994 an Irish reference preparation for bovine tuberculin PPD was calibrated against the International Standard and since then Ireland has used a standardized bovine tuberculin PPD at or about 30,000 I.U./ml PPD (+/-10%) and avian tuberculin 25,000 I.U./ml PPD (+/-10%) matched within 500 I.U./ml to ensure optimum specificity and uniform performance. Tuberculin potency is periodically validated in naturally infected tuberculous cattle against the Irish reference preparation. The Single Intra-dermal Comparative Tuberculin Test (SICTT) is the most specific tuberculin test available and the greater the potency of bovine tuberculin relative to the

1. Tuberculin PPD (bovine or avian) is a preparation obtained from the heat-treated products of growth and lysis of *Mycobacterium bovis* or *Mycobacterium avium* (as appropriate) capable of revealing a delayed hypersensitivity in an animal sensitised to microorganisms of the same species.

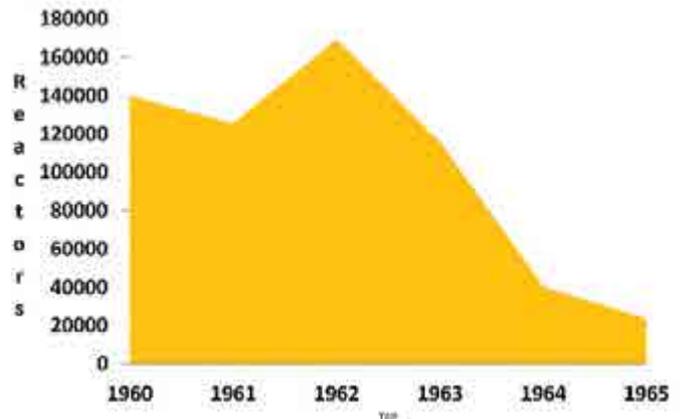

FIGURE 1: Bovines removed as reactors to the tuberculin test, 1960 to 1965.

In Ireland an initial pilot programme to assess levels of infection commenced in 1950. A voluntary bTB eradication programme followed in 1954 and in 1957 the compulsory programme started, on an area basis, extending nationwide by 1962. In October 1965 the Government of the day optimistically, based on the observed downward trend, (Figure 1) declared the country virtually free of tuberculosis.

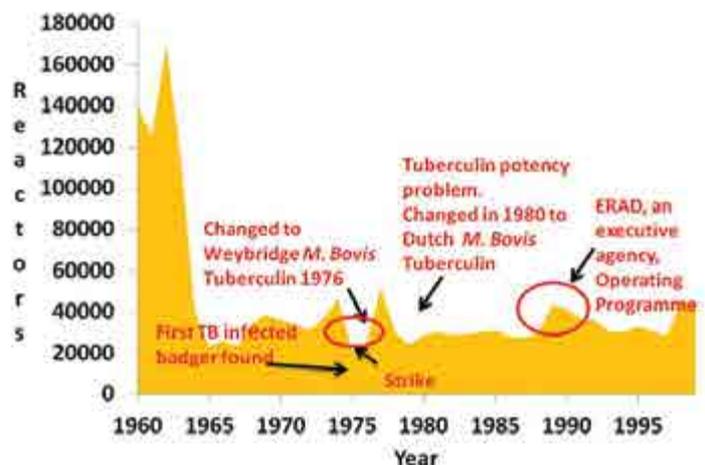

FIGURE 2: Bovines removed as reactors to the tuberculin test, 1960 to 1999 with key events depicted.

avian tuberculin the less the specificity and the greater the sensitivity of the SICTT and vice versa. It was only on accession to the EEC by UK, Ireland and Denmark that the SICTT was incorporated, by Directive 80/219/EEC, into the EU Trade Directive which originally had only allowed use of the Single Intradermal Tuberculin test (SIT).

The Irish bTB eradication programme, has evolved as the concept of understanding and managing risk developed and while the basic principles laid down in the 'trading' Directive, continue to be met, the programme has been enhanced by additional measures in an effort to achieve eradication. Multiple reviews and copious recommendations which the then current wisdom perceived as the reason for the 'stalled programme' led to the introduction of various other controls. Many of these controls, such as extended status withdrawal for infected herds have been later abandoned as not providing any significant benefit to bTB Eradication.

In 1988, ERAD, a specialised executive agency was established to implement a vigorous four-year eradication programme. The board, represented various interests, including farmers and veterinarians, involved in TB eradication. A strategic multi-annual plan was developed, a budget provided and an ambitious target set to reduce the reactor numbers by 50%. Herds/areas were categorised according to disease incidence, with a specific strategy applied to each category and there was a huge increase in the number of tests performed. However, as can be seen from Figure 2, despite an increased reactor identification and extraction rate throughout the four years of the programme, the reactor numbers thereafter stubbornly remained at the ~30,000/annum levels.

The Tuberculosis Investigation Unit, was established in 1989, based in the then Veterinary Faculty in University College Dublin. The function of the unit was to investigate the factors that militate against the eradication of tuberculosis in cattle at the national or regional levels, and to identify means of improving the rate of eradication. *In association with field and laboratory based operations, there has since been an extensive programme of research (much of it epidemiological) to address gaps in knowledge, to objectively evaluate alternative strategy options, and to critically assess the implementation of disease control strategies.* Although the role of its replacement the Centre for Veterinary Epidemiology and Risk Assessment (CVERA) has now broadened considerably, it continues to manage and analyse retrospective and concurrent data relating to the occurrence of tuberculosis in cattle and to undertake projects to answer specific questions and assess epidemiological elements, various components of infection and the role of wildlife; the elements of BTB diagnosis (Tuberculin skin test, Interferon- γ assay – introduced to Europe at the initial M.bovis conference held in Dublin in 1991, ELISA, anamnestic ELISA etc.) and developments therein. The effect of a recent tuberculin test and the nature of the response to tuberculin test have been elucidated, strain typing of M. bovis undertaken and the role of environmental mycobacteria investigated. A 'Singleton Protocol' was developed to provide a means for rapid derestriction of herds where TB is considered unlikely epidemiologically and there is no confirmation at laboratory level.

Until 1996, a pre-movement test was required, then abandoned as neither cost effective nor contributing to bTB eradication. There was also little evidence of onward transmission of infection from moved infected animals. Accordingly, with some herd/animal risk based exceptions, animals may move for up to 12-months from the date of their last SICTT. Breakdown severity, during a bovine tuberculosis episode, is a predictor for future herd breakdown as is contiguity to a herd undergoing a high-risk breakdown, defined as within herd acquisition and spread of TB (≥ 2 infected animals). Therefore, herds with a high risk history and their contiguous herds are tested more frequently and the window of opportunity for movement from such herd is curtailed. Inconclusive reactors, remain a risk for life and therefore notwithstanding that they may pass multiple SICTTs subsequently they are confined to their herd of disclosure for life.

Knowledge of disease epidemiology (including causation and, if infectious, transmission and maintenance of infection) is central to the development of control strategies. In 1958 Francis, speaking of the difficulties in final eradication of bTB recommended that to achieve complete success tuberculosis had to be dealt with in all species. In 1974 the first infected badger (*M. meles*) was detected in Ireland and by the mid 1980s infected badgers had been found throughout the whole country. Over the subsequent 30 years, the role of wildlife in bovine tuberculosis became clearer as the same strain types of *M. bovis* were detected in both badgers and cattle. Tuberculosis was described as a re-emerging disease at the interface of domestic animals and wildlife by Palmer who cautioned that it will not be possible to eradicate *M. bovis* from livestock until transmission between wildlife and domestic animals is halted, which will require collaboration between stakeholders. Some wildlife species, principally the badger in the United Kingdom and Ireland, the Australian possum in New Zealand (but not Australia), and water buffalo in Australia, have been recognised as significant reservoirs of *M. bovis* with endemic self-maintaining infection in these species constituting a major obstacle to disease control programmes. In Australia, elimination of wild water buffalo, and feral cattle from endemically infected areas was a major component of the eradication campaign in, now bTB-free, Australia. New Zealand similarly employed strict possum population control measures, and very considerable progress has been made. Michigan State in the USA had been TB-accredited-free from 1979, with no tuberculous cattle detected for 5 years. However, in 1994 a hunter found a tuberculous deer and it is accepted that endemically infected deer were spilling back infection to local cattle farms. Consequently on-farm risk mitigation measures against TB transmission from deer to cattle are recommended. TB has been reported in wildlife in a number of European countries struggling to eradicate tuberculosis in bovines. It is becoming increasingly obvious that wildlife populations with endemic TB pose a significant constraint to final TB eradication in cattle. In epidemiological terms, disease can persist in some wildlife species, creating disease reservoirs, if the basic reproduction rate (R_0) and critical community size (CCS) thresholds are achieved. Thus eradication efforts require elimination of *M. bovis* transmission between wildlife reservoirs and cattle. However, at present, the sympatric wildlife reservoir is the major impediment to the eradication of bTB in Great Britain, and Ireland and to ignore this impediment would be tantamount to dismissing one of the basic tenets of eradication.

DAFM commissioned a number of research projects to accurately estimate the contribution of the tuberculous badger population. The results showed a reduction in the number of reactor cattle with a significant difference between the removal and reference areas in each study area. Furthermore the herd breakdown risk was significantly lowered in the culled relative to the control areas for up to a decade after the end of the trial. Ireland and the U.K. are collaborating to develop a vaccination strategy for badgers in order to progress bTB eradication. BCG vaccine is protective in captive badgers. Field trials will elucidate the impact of vaccine in wild populations. Pending vaccine development, manufacture and licensing for general delivery to a wild population, Ireland operates a non-selective badger cull regime directed, since 2004, to areas with a chronic history of bTB. Culling reduces infected badger density and overall TB prevalence in badgers to minimize spill over to cattle. There has been an overall drop in mean TB prevalence in culled badgers from 26% in 2007 to 11% in 2011. The decline in infection levels in cattle is at least partly attributed to the culling programme. A recent simulation model also supports the hypothesis that culling strategies appeared to be the most effective method for TB control in badgers. A reduction in both badger population density and TB infected badgers followed by long term vaccination may be effective in reducing risk to cattle herds. Pending oral vaccine development culling is gradually being replaced by BCG injection with a non-inferiority study commenced in 2014 to determine if allowing a vaccinated badger population to rebuild in previously culled areas is viable in terms of levels of bTB in sympatric cattle.

TABLE 1: Cattle Population and Tuberculin testing statistics over four decades; five-yearly from 1960-1995, then yearly.

Year	Herds	No. of newly Restricted Herds	% Herd incidence	Cattle Population Tested	Number of Animal Tests	No. of Reactors	% Animal Disease Prevalence	APT **
1960	~250000			4,683,700	*	139,881	2.99	-

2012	115,787	4,856	4.3	6,145,469	8,534,677	18,476	0.30	2.16
2013	115,765	4,430	3.9	6,146,958	8,474,961	15,612	0.25	1.84
2014	114,508	4,111	3.6	6,115,528	8,445,262	16,145	0.26	1.91
2015	115,091	3,823	3.32	6,321,196	8,429,602	15,317	0.24	1.82

* Accurate figures for the total number of animal tests per year were not available until 1978.

** The APT is used as a measure of the incidence of disease compared to the level of testing being carried out. The APT figures represent the number of reactor animals disclosed per 1,000 tests.

*** The RPT is used as a measure of the incidence of disease compared to the total population of animals. The RPT figures represent the number of reactor animals disclosed per 1,000 animals.

The trend in cattle population and disease incidence since 1960 is presented in Table 1. In 1954, when the eradication programme commenced, there were some 250,000 herds with 4.5 million cattle registered in Ireland with an animal test reactor incidence of 17% (cows 22%, other cattle 8%). Over the course of the programme to date, in excess of 300M individual animal tuberculin tests have been conducted. Human zoonotic tuberculosis is now uncommon in Ireland.

In summary Ireland has as the basis of the modern and ever evolving bTB eradication programme:

- Mandatory herd (epidemiological unit) registration,
- Individual bovine animal unique identification,

- Individual animal passport
- A computerised Animal Identification and Movement system (AIM)
- An Animal Health Computer System (AHCS)

A comprehensive programme of disease surveillance including:

Farm-based testing:

- mandatory SICTT annual test of all herds, testing herds contiguous to or otherwise epidemiologically linked to infected herds, check-tests of at risk herds and herds in 'at-risk' areas, a herd test six-months following restoration of status, and
- Veterinary inspection of all bovine carcasses in abattoirs.

Figure 3: I

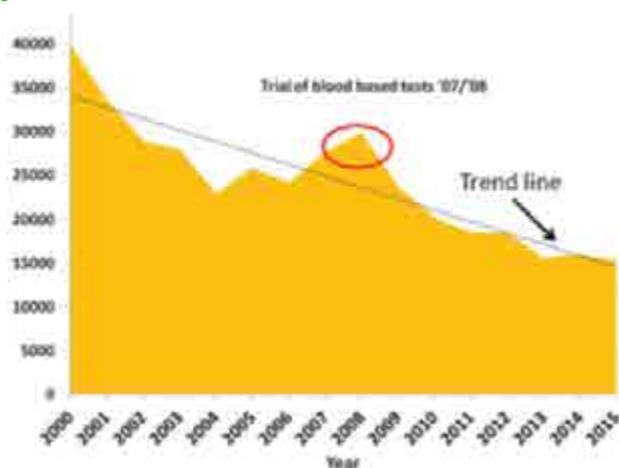

Figure 3: II

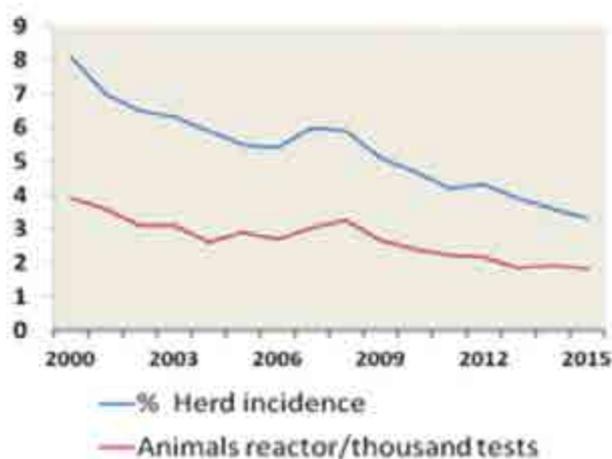

Figure 3: III

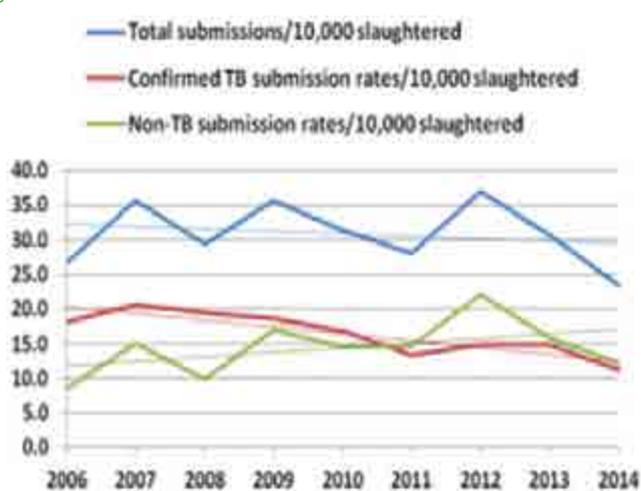

Figure 3: IV

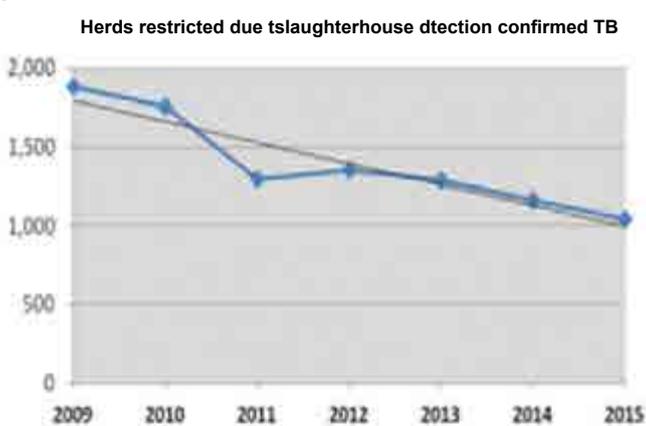

Figure 3: Key performance indicators

- I. Animals removed as reactors under the bTB eradication programme 2000-15 with trendline;
- II. Herd incidence and Animal reactor per 1000 animals tested SICTT (APT) 2000-15
- III. Slaughterhouse lesion submission rates, suspect and confirmed 2006-2014
- IV. Herds restricted due to slaughterhouse detection of confirmed bTB 2009-14 with trendline.

Disease controls

- severe interpretation of SICTT when infection established;
- Interferon-γ assay, ELISA and anamnestic ELISA use in problem herds;
- prompt removal of reactors;
- epidemiological investigations;
- outward movement limitation from H-breakdown herds post-status restoration
- SICTT at ~60-day intervals until two clear tests in succession;
- hygienic controls on infected holdings and vehicles;
- trace of (potentially) TB infected animals from and forward to other herds;
- herd depopulation where TB levels or duration indicates it is necessary to clear the herd and/or protect the neighbourhood;
- restriction of contiguous herds >4-months since previous test; and
- Confinement of inconclusive reactors to herd of disclosure for life.
- Badger population controls (culling), minimum 3-years followed by gradual replacement of cull areas by badger vaccination (BCG by injection)

Compensation

- market valuation of reactors but with a maximum allowable valuation.
- Income and hardship support payments

Quality control

- potency assay of tuberculin in naturally infected cattle
- SICTT conducted by specifically authorised Veterinarians;
- monitor on equipment, test performance and results for each testing Veterinarian;
- monitor on abattoir surveillance for TB suspect lesions
- computer monitor of testing performance,
- 'Singleton Protocol' monitor on reliability of SICTT and progress towards bTB eradication
- QC checks on testing facilities; and reactor animal examination including use of Interferon-γ assay.

The Interferon-γ assay is used as an adjunct to the tuberculin test, particular since 2012, so as to identify potential infected animals for removal. Since 2000 bTB levels, have been declining, herd incidence, number of reactors (notwithstanding increased removal of Interferon-γ assay positives) and number of detections of TB lesions at slaughter in non reactor cattle are all indicative that progress is being made towards bTB eradication. Figure 3

Conclusion

Full compliance with EU Directive 64/432/EEC, ensures that Irish farmers meet the conditions for trade within Europe and beyond. Recent progress is reflected in the education in bTB levels as measured by the key performance indicators. The consistent application of the programme ensures that bTB is no longer the scourge it was.

Eradication of bTB is the ultimate objective of the national programme and considerable progress has been made over the last 15-years, sufficient to support the goal of bTB eradication in 2030. Realistically, however, this can only be achieved by simultaneously tackling the disease in all the maintenance hosts in which the disease is endemic and which share the same environment as bovine animals. As disease levels decline the controls where herds and animals are detected infected will perform become increasingly severe until eradication is finally achieved.

National Cattle Health Programmes- an Irish Perspective

David Graham MVB PhD MRCVS

Animal Health Ireland, 4-5 The Archways, Carrick-on-Shannon, County Leitrim, Ireland

www.animalhealthireland.ie
david@animalhealthireland.ie

Introduction

The agri-food sector is Ireland's largest indigenous industry, contributing €26 billion in turnover and generating 12.7% of merchandise exports. The sector accounts for 8% of total employment, and makes a particularly significant contribution to employment in rural areas. Food and beverage exports increased to a record value of €10.4 billion in 2014, representing an increase of 4% on the previous year and a 45% increase since 2009.

Ireland has a national cattle herd of some 6.9 million head. The annual calf crop is approximately 2.2 million, with similar proportions born in dairy and beef herds. There are approximately 116,000 cattle herds, of which 17,000 are dairy enterprises, 61,000 are beef breeding (suckler) enterprises and the balance are categorised as beef (28,400) or "other" (9,500). Husbandry systems are largely based on production from grass and as a consequence there is a significant bias toward spring calving to match grass growth, with 83% of calves born in the first half of the year and 43% in February and March alone.

Cattle and milk products, together account for approximately 70% of agricultural output. Given Ireland's high degree of self-sufficiency in these products, it is the international, rather than the domestic, marketplace that is, in large measure, their final destination.

Reflecting the importance of the agri-food sector to the national economy, there have been two significant strategy documents developed in recent years to guide its development, with particular emphasis on the cattle sector. The first of these, Food Harvest 2020 (<http://www.agriculture.gov.ie/agri-foodindustry/foodharvest2020/>), established significant growth objectives for the sector in the period 2010 to 2020, including:

- Increasing the value of primary output of the agriculture, fisheries and forestry sector by €1.5 billion;
- Improving the value-added in the sector by €3 billion;
- Achieving an export targets of €12 billion for the sector
- Increasing the volume of milk production by 50%;
- Adding 40% to the value of the beef sector.

Building on the progress already made against these targets, the Department of Agriculture, Food and the Marine (DAFM) recently launched Foodwise 2025 (www.agriculture.gov.ie/foodwise2025) a national ten year strategy for the agri-food sector to 2025, setting new goals of 70% and 85% increases in the gross value-added of the sector and of the value of exports respectively relative to a 2012-baseline. Key actions in relation to further development of people, innovation, market development and competitiveness are identified with sector-specific recommendations that also address the need for environmental, social and economic sustainability.

Both of these documents recognise the key contribution which improved animal (cattle) health can make to achieving these goals.

Animal Health Ireland (AHI)

AHI (www.animalhealthireland.ie) was established in 2009 as an industry-led, not-for-profit, partnership between livestock producers, processors, animal health advisors and government to provide national leadership and co-ordination of animal health issues that are not regulated at national or European Union-level (More et al., 2011) but until recently

there has been no national coordination of non-regulatory animal health issues. This gap has recently been filled with the establishment of Animal Health Ireland (AHI).

Prior to this, public-private sector interaction in animal health policy in Ireland was typified by government-led and -funded programmes such as those for tuberculosis, brucellosis and bovine spongiform encephalopathy, reflecting the significant risks posed to public health and market access and consequently the predominance of public good arising from their control and eradication.

AHI's vision is to be recognised as a world-class resource enabling Irish farmers and the agri-food industry to achieve and maintain the highest international standards of animal health, to improve the profitability and sustainability of their enterprises and to enhance the value and competitiveness of Irish products in the marketplace. Given the importance of the sector, AHI has to date only addressed diseases of the cattle industry.

One of AHI's first tasks was to identify and prioritise the cattle health challenges facing this sector. This was addressed through a policy Delphi study with national experts and surveys of beef and dairy farmers to prioritise diseases and conditions based on cost (to farmers, to agribusiness), impact (on farmers and their animals), international perception and impediment to market access (More et al., 2010) national animal health services have been a government, rather than an industry, responsibility. In 2009, Animal Health Ireland (AHI). The top seven disease priorities included both infectious agents (infectious bovine rhinotracheitis [IBR], bovine viral diarrhoea [BVD], Johne's disease [JD]) and multifactorial conditions (infertility, udder health, lameness and diseases of young calves).

Based on this work, and taking into account both the probability of achieving eradication (or significant control) of each disease within reasonable timeframes and the resources and expertise available, AHI initially established and rolled out four prioritized programmes for BVD, somatic cell count (SCC; CellCheck programme), JD and IBR with these being incorporated as key activities in a three-year (2012-2014) strategic plan with defined strategic objectives and annual targets. These have been carried forward into a further three year (2015-2017) strategy document, supplemented with an additional programme to capture and use abattoir data on liver and lung lesions (Beef HealthCheck). In addition, activities are undertaken under four further work areas: parasite control, CalfCare, biosecurity and animal health economics, with outputs either supporting priority programmes or equipping farmers, vets and advisors to achieve change at individual farm level.

Reflecting the partnership ethos of the organisation, and the greater, albeit variable, private good that accrues from addressing these diseases, funding is provided by a range of private and public sector stakeholders, including dairy and beef processors, farmers' organisations and livestock marts, professional, advisory and support services and government and state agencies.

For each priority programme or work area, AHI has established a technical working group (TWG) of experts tasked with the development of detailed factual resources, development of tools to aid the control or eradication of the disease at farm level, development of policy options where appropriate for disease control/eradication and identification of areas for future research.

Where a decision has been taken to formalize a programme at national level, on either a voluntary (JD, Cellcheck) or a compulsory (BVD) basis, a cross-industry Implementation Group (IG) drawn from stakeholder organisations and chaired by AHI has also been convened to oversee their delivery. Consideration of the costs and benefits of a national approach, and allocation of these to different sectors including farmers, processors and government, has been identified as a key factor guiding decision making by IGs, and several studies have been carried out in this regard (Geary et al., 2013, 2012; Stott et al., 2012) cases treated, and

on-farm practices around mastitis management. The Moorepark Dairy Systems Model, which simulates dairying systems inside the farm gate, was used to carry out the analysis. The cost components of mastitis that affect farm profitability and that were included in the model were milk losses, culling, diagnostic testing, treatment, veterinary attention, discarded milk, and penalties. Farms were grouped by 5 BMSCC thresholds of $\leq 100,000$, $100,001-200,000$, $200,001-300,000$, $300,001-400,000$, and $> 400,000$ cells/mL. The $\leq 100,000$ cells/mL threshold was taken as the baseline and the other 4 thresholds were compared relative to this baseline. For a 40-ha farm, the analysis found that as BMSCC increased, milk receipts decreased from $\approx 148,843$ at a BMSCC $< 100,000$ cells/mL to $\approx 138,573$ at a BMSCC $> 400,000$ cells/mL. In addition, as BMSCC increased, livestock receipts increased by 17%, from $\approx 43,304$ at a BMSCC $< 100,000$ cells/mL to $\approx 50,519$ at a BMSCC $> 400,000$ cells/mL. This reflected the higher replacement rates as BMSCC increased and the associated cull cow value. Total farm receipts decreased from $\approx 192,147$ at the baseline ($< 100,000$ cells/mL). Social science studies are also increasingly used to gain a better understanding of factors that either prevent or motivate changes in behaviour in relation to the various programmes.

AHI PROGRAMMES

CellCheck

The CellCheck programme was originally developed in response to industry demand for a sustainable and coordinated approach to improving mastitis control. It was launched in 2010 and has focussed on building awareness, knowledge and capacity to facilitate improvements in mastitis control through the development of independent, science-based resources and training for both service providers and farmers. These have facilitated engagement between service providers, and the development of regional networks. CellCheck also enhances the regional support network and the consistency and quality of information available to farmers in relation to mastitis control. There has also been an increasing emphasis on working with industry partners to ensure that suppliers receive clear, consistent signals about the desired quality of raw milk produced in Ireland. CellCheck recognises that enabling the industry to work together to deliver consistent information and mastitis control solutions is the most sustainable model. It is also important for milk suppliers to recognise the role that all disciplines can play in improving mastitis control. Based on the premise that mastitis is a multifactorial problem, and therefore best addressed by a multidisciplinary approach, CellCheck is working to develop the capacity of the various service provider groups – vets, farm advisers, dairy co-op milk quality advisers and milking machine technicians – to work collectively to provide solutions and support for dairy farmers.

The establishment of a national SCC database, which allows trends in the national herd to be examined, and the impact of the programme to be evaluated, has been another key achievement of the programme.

The current goal set by industry is that 75% of the milk supplied by Irish farmers will have an SCC of 200,000 cells/mL or less by 2020.

Significant progress has already been made with data from milk recording herds showing that in 2015, 61% of herds had an annual average SCC of $< 200,000$ cells/mL, compared to 26% of herds in 2010. Bulk tank data from the national SCC database shows a similar trend, with the proportion of herds and milk volume with an annual average SCC $< 200,000$ cells/mL increasing from 39% to 45%, and 46% to 55% respectively, between 2013 and 2014.

Johne's Disease

Following a review of control programmes elsewhere (Geraghty et al., 2014) control activities and monitoring components of programmes in Australia, Canada, Denmark, the Netherlands, the United Kingdom

and the United States of America were individually reviewed. Factual accuracy of each review was checked by individuals involved in the respective programmes before the reviews were condensed and combined into a single document presented here, with the complete reviews of each programme available as supplementary material. There was considerable heterogeneity in key aspects of control activity design including goals, responses to declining participation, herd classification, recommended control measures and associated test requirements. The data presented will be of interest to organisations that are involved in developing new or existing regionally coordinated BJD control activities. (Geraghty et al., 2014, the JD TWG developed the technical details of a dairy Johne's disease control programme (JDCP). Following consideration of these by the JD IG, a pilot programme was initiated in 2013 with the following objectives:

To test, evaluate and refine the various programme components that would be required to support a future, extended JDCP with the following goals:

Bio-exclusion

To identify herds that test negative for JD and provide them with the knowledge and professional support to allow them to increase their confidence over time of being free of infection and to protect their herds from the on-going risk of introduction of this disease.

Bio-containment

To provide infected herds, or those having a low confidence of freedom from infection, with the knowledge and professional supports to allow them to control and reduce the prevalence of the disease over time and ultimately to achieve a high confidence of freedom from infection (bio-containment).

Market reassurance

To underpin the quality of Irish dairy and beef produce in the international marketplace.

To generate information on the control of JD on Irish dairy farms, including that relating to the economics of the disease and its control, to assist the design of a future, extended JDCP.

Key components of the pilot programme include herd screening of eligible animals, limitations on the sale of JD-positive/inconclusive animals and an annual on-farm veterinary risk assessment and management planning visit conducted by an approved veterinary practitioner.

The JD TWG has developed a system of herd categorisation, based on test results and movement data, which provides a measure of the degree of confidence that any given herd is truly free of infection at a particular point in time and a framework by which to evaluate progress in controlling the disease at individual herd and aggregate level (More et al., 2013) and separate sub-programs are followed for test-positive and test-negative herds. However, a test-negative herd result does not necessarily equate to JD freedom for reasons relating to disease pathogenesis and available diagnostic tests. Thus, in several countries, JD control programs define test-negative herds as having a "low risk" of infection below a specified prevalence. However, the approach is qualitative, and little quantitative work is available on herd-level estimates of probability of freedom in test-negative herds. This paper examines the effect over time of alternative testing strategies and bio-exclusion practices on JD risk in test-negative herds. A simulation model was developed in the programming language R. Key model inputs included sensitivity and specificity estimates for 3 individual animal diagnostic tests (serum ELISA, milk ELISA, and fecal culture).

A review of the pilot programme will be carried out in 2016 to determine the next steps in terms of its extension or expansion.

IBR

The programme aims to eradicate IBR from the national herd, subject to a positive cost-benefit analysis (CBA) and a mandate from AHI stakeholders. Work is ongoing on the CBA, including modelling of options for a national programme. The CBA will then be presented to AHI stakeholders and a decision taken on whether or not to progress to a national eradication programme, with a target date of commencement by 2019.

Beef HealthCheck

This is a new programme which is being developed by AHI in conjunction with industry partners and DAFM. The objectives of the programme are firstly to develop tools to assist farmers and their veterinary practitioners to control losses due to liver fluke and pneumonia through capture, analysis and reporting of abattoir data and secondly to provide data that will contribute to the development economic breeding indices that address incorporating health and disease. Health information is captured by veterinary inspectors using touch-screen technology during the public health inspection process in slaughter premises. This information is provided directly to farmers in batch-level reports and is also transferred to a central programme database (www.icbf.com) which is currently being developed to provide farmers and their veterinary practitioners with tools to assist them with herd health management as well as providing national-level data for monitoring and evaluation, including the losses associated with these conditions, improved fluke forecasting and genetic analyses.

BVD

Prior to initiating a national eradication programme, a review of other European programmes was undertaken (Barrett et al., 2011), followed by a national consultation and a cost-benefit analysis (Stott et al., 2012), before a decision to proceed was taken. A range of factors relating to the industry (herd size, type, calving profile, herd contacts, level of movements), logistics (sample collection, transport, laboratory capacity, availability of a national database), socio-economics (costs and benefits at farm and national level, farmer awareness and support), disease (prevalence) and political factors (support of government, farming and veterinary organisations) were also taken into account in deciding to proceed with the programme and on its structure and implementation.

The programme began with a voluntary year in 2012 (Graham et al., 2014) during which approximately 600,000 of the 2.1 million calves born were tested. This provided an opportunity to test the programme, to learn from farmers' experiences (Devitt et al., 2014) and for industry to demonstrate commitment to the programme. As a result, the BVDIG requested government to introduce legislation to enable a compulsory programme from 1st January 2013.

All herd owners must collect and submit ear tissue samples (collected using the official identity tag or a supplementary tag) to a designated laboratory, from where they are transferred on a daily basis to a central database (www.icbf.com), which then issues results to farmers by SMS message. Results are also shared with government databases, preventing movement of animals without a negative result.

2013 provided baseline national data, with 0.67% of calves born considered to be persistently infected (PI) and 11.3% of herds having positive results. In 2014 and 2015 these levels fell to 0.46%/7.6% and respectively, and 0.33%/5.9% in 2015. Further significant progress has been made in 2016, with only 0.14% of 700,000 calves born in January and February considered to be PI.

While immediate removal of PIs has been encouraged, their retention by some farmers in the absence of compulsory removal and compensation at notional market value has been an ongoing problem. Several studies and modelling work have (Graham et al., 2015a; Graham et al., 2015b), reinforced the importance of prompt culling. A number of measures,

including the provision of limited financial supports, the exclusion from other government-funded agriculture programmes of herds that retain PIs, the imposition of movement restrictions, the notification of neighbouring herds and investigation of herd breakdowns funded under the Rural Development Plan have all contributed to an improvement in the rate of removal.

After three years of testing, more than 98% of animals in breeding herds now have a known (negative) status, acquired either directly based on their having been tested within the programme or as indirectly through their having produced one or more negative calves. Based on these results, more than 54,000 breeding herds (%) have acquired a negative herd status.

Conclusions

AHI has made significant progress in developing national cattle health programmes since being established in 2009 which have made a significant contribution to the delivery of specific objectives in Food Harvest 2020 and Foodwise 2025. The achievements to date owe much to active collaboration amongst key stakeholders, guided and led by AHI, and supported by a multi-stranded, comprehensive communications strategy. The AHI model shows the potential and challenges for industry-led programmes built on consensus to deliver real progress.

An ultimate goal of disease control programmes is to accurately predict future events such that measures to prevent disease can be identified in advance. In this paper we consider the current context of mastitis control on dairy farms and discuss future possibilities where predictive biology may provide insights into the prediction and prevention of disease.

Context of mastitis control

Mastitis remains an important condition of dairy cattle on a global scale. As well as causing substantial financial losses (Halasa et al., 2007), changes to the quality and storage characteristics of milk (Barbano et al., 2006) and a negative impact on cow welfare (Milne et al., 2003), with the increasing concerns over the sustainability of farming and global food security, the environmental impact, wastage and inefficiencies associated with mastitis have come sharply into focus (Hospido and Sonesson, 2005). In the UK, for example, the milk retrieved if half of all clinical mastitis cases could be prevented would be sufficient to supply 1.5 million UK consumers per year. Furthermore, mastitis is one of the most common reasons for use of antimicrobials in dairy cows. With current concerns regarding the emergence of antimicrobial resistance in agriculture, there is a widespread drive to reduce use of antimicrobials in food producing animals.

Brief history and current approaches to mastitis control

Generic approaches to mastitis control have been discussed and implemented for many decades. At the start of the 19th century, mastitis had been identified as an important condition and the pathogens associated with mastitis were being worked out (Henderson et al., 1904). By 1918, sources of infection and routes of transmission were being considered in the hope that infections could be reduced (Jones, 1918). Antibacterial treatments for mastitis were used in the 1930s (Stevenson, 1939) and it was already noted in 1963 that mastitis was the most common reason for the use of antibiotics in cattle (Uvarov, 1963). By the early 1960s, information on the spread of contagious mastitis was being defined and five major elements of mastitis control were put together as a 'Five-Point Plan' (Neave et al., 1966).

Whilst we have moved on from this era to some extent, it is perhaps surprising that there are not more high-tech solutions for mastitis control. Whilst parlour automation has increased and improved, and in many developed dairy nations, classical contagious mastitis pathogens are now at low prevalence, there remains a reliance on generic control strategies that originated in the 1960s. In terms of barriers to implementing mastitis control on farm, there has been recognition that understanding human behaviour including how to 'change the minds and actions' of people involved with mastitis control is crucial (Jansen et al., 2010, Higgins et al., 2012, Jansen and Lam, 2012).

In general, approaches to providing advice on mastitis control might be divided into two types; 'reactive' and 'prospective'. Reactive mastitis management reflects a veterinary practitioner, advisor or referral service being asked to assess a problem situation, whether long standing or a sudden outbreak. Such investigations often include analysis of farm records and current management. Samples may be taken to assess pathogen involvement and may include sub-species (strain) typing to pinpoint bacterial sources (Munoz et al., 2007) A prospective approach

to mastitis control incorporates many of the principles of herd health management; setting of goals, on-going monitoring of disease and updating of management practices when goals are not achieved (Green et al., 2012).

The problem with both reactive and prospective approaches to mastitis control is that they rely on current farm information to define what is happening and therefore what to change. In this sense, they are both in fact 'reactive'. To transform mastitis control, an ideal situation would be to make use of current data to predict what is likely to happen in the future, and to predict different farm outcomes that would be expected in light of different decisions; such an approach could be termed 'predictive' mastitis control.

With advances in on-farm technologies, scientific approaches and data handling capabilities, opportunities in this field are becoming reality. We give four examples below in which research into biological processes aims to make predictions about mastitis and its control.

Predictive biology; examples in mastitis control

1. Predicting cow susceptibility to mastitis

Predicting the susceptibility of a cow to intramammary infection can be of use in the management of mastitis, not only in terms of breeding decisions, but also to allow individualised management practices. To some extent, disease susceptibility will be dictated by genetic influences and 'genomics', the prediction of phenotype from genomic markers, is possibly the field in which prediction of performance is most advanced. Although understanding genetic determinants of animal disease is at a relatively early stage, rapid advances are occurring in this area and there should be opportunities to improve the understanding of cow resistance to mastitis, as long as high quality phenotypic information is available. For mastitis, it is unlikely that one or a few genes will be responsible for most of the variation in cow mastitis resistance, and thus a truly polygenic approach will be necessary. It seems likely from studies to date that an integrated polygenic approach to genome investigation is likely to be beneficial in explaining the overall impact of genetic variability; similar studies have proved invaluable in deciphering the genetic involvement for human diseases (Lin, 2015, Musliner et al., 2015). Susceptibility to mastitis, however, is unlikely to be solely dependent on an animal's initial genetic make-up. Environmental influences alter susceptibility, partially through epigenetic changes and partly through direct physiological modifications. Evaluation of how the environment interacts with the cow's expressed genome may allow bespoke, individual management of animals.

An example of a direct modification of disease susceptibility for mastitis is the microbial community (microbiome) in the mammary gland. It is increasingly clear that the health and well-being of mammals is related to their colonising microbial communities (Ley et al., 2008). Some microbiomes might offer protection from infection by occupying niches that could otherwise be occupied by pathogens or by priming the immune system to respond to infection (Kau et al., 2011). The risk of disease may be influenced by the mammary microbiome and understanding this community could provide a new angle on the control of mastitis (Hunt et al., 2011). In a 2012 paper on the microbiome of the bovine mammary gland, differences were identified between the microbiomes of healthy and infected quarters, indicating microbiomes that varied by disease state (Oikonomou et al., 2012) An understanding of the mammary microbiome may enable temporal predictions to be made about individual or group resilience to mastitis and facilitate manipulation of this community to optimise mammary gland health. Research in this area is on-going.

2. Pathogen phenotypes; sub species predictions

The pathogens that cause mastitis in dairy cows are generally recognised and considered at species level in terms of their phenotypic characteristics on farm. For example, phenotypic traits include being

associated with 'contagious' or 'environmental' transmission, chronic or acute disease, long or short duration rise in somatic cell count (SCC) or the carriage of specific antimicrobial resistance (AMR) genes. However, it is clear that such characteristics will be different for different sub species within the major species of mastitis pathogens and therefore linking sub species to phenotypic infection patterns will help in terms of making predictions on farm.

For strain typing to be effective as a predictive technology, fast throughput systems, portable between laboratories will be needed that can accurately differentiate clinically important strain phenotypes. An example of such a system is Matrix assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS). MALDI-TOF-MS produces a protein 'fingerprint' of ribosomal proteins quantified as the amount of each protein present, defined by its molecular weight. MALDI-TOF-MS is routinely used in many microbiological laboratories for species determination of bacteria and fungi, and can also be used for subtyping of bacteria. It has also been used successfully to differentiate bacterial sub species according to phenotype (Moura et al., 2008, Nagy et al., 2013).

We have recently conducted projects using MALDI-TOF-MS and multilocus sequence typing (Davies et al., 2016) to attempt to differentiate phenotypes of *S. uberis* putatively associated with either apparently 'contagious' or 'environmental' transmission. Results will be presented.

3. Predicting cost effectiveness of management changes

Since resources will be limited on a dairy unit, when assessing competing disease control strategies, it would be valuable if interventions could be evaluated and prioritised not only according to probable efficacy, but also to likely return on investment. The effective use of farm resources requires an understanding and weighing up of the probable outcomes of implementing one intervention rather than another. This is a dilemma faced by farm advisors and decision makers and it would be useful when deciding whether to employ resources in one area, to be able to compare, for example, the probability of a net benefit in that area with all other potential areas where resources could be employed (Briggs and Gray, 1999). This idealised approach is difficult to achieve in terms of mastitis control because data from intervention studies to assess the efficacy of different control policies is sparse. In reality it is of limited use to estimate some 'average' cost benefit of an intervention, rather we would like to know the probability of achieving different levels of cost benefit. An approach to probabilistic cost-effectiveness analysis adopted in the human medical field is a Bayesian method termed comprehensive decision modelling (Cooper et al., 2004, Ades et al., 2006a and b, Griffin et al., 2008). An example of this approach, applied to the cost effectiveness of mastitis control interventions, will be described.

4. Predictions from simulation

Our final example uses the technique of data simulation - this is a method to combine many sources of information to evaluate many different 'what if' scenarios. Simulation-based techniques can be particularly useful for the evaluation of hundreds of thousands of theoretical sets of farm circumstances when obtaining the equivalent experimental information would be impractical and expensive. It is also of considerable value to assess the impact of uncertainty in research findings, a critical area often overlooked. Simulation based studies use parameters derived from 'real life' (where possible) and combines these in ways to make onwards predictions. The goal is to identify patterns in the simulated scenarios to identify circumstances when specific control measures are likely (or not) to be useful and to rank the measures in order of usefulness. A major advantage of simulation studies is that parameters for the simulation can encompass a wide variety of sources such as previous research or expert opinion, and synthesise these to produce insights not previously captured.

During the conference, we will provide two recent examples of simulation

studies that have been used to improve the understanding and make predictions about mastitis. In the first, the impact of mastitis on herd reproductive performance was evaluated (Hudson et al., 2015) and in the second, the cost effectiveness of mastitis treatment was assessed with and without the use of an 'on farm culture' (OFC) technique (Down et al. submitted).

Conclusions; Big data – into the future...

The quantity of data and technology available on-farm will continue growing rapidly; opportunities will exist to harness these to make useful biological predictions. For instance, can we integrate information on cow susceptibility, pathogen behaviour and farm interventions to simulate different choices and offer 'real time decision support'? Essentially this would mean identifying the best decision (e.g. management change) in a given set of circumstances and its probability of success. The key will be to ensure results are clear, relevant and accessible to the end user. Is this the future for mastitis control?

Economics for the veterinary practitioner: From burden to blessing

Henk Hogeveen^{1,2}, Felix J.S. van Soest¹ and Mariska van der Voort¹

¹Business Economics group, Wageningen University, the Netherlands

²Department of Farm Animal Health, Faculty of Veterinary Medicine, Utrecht University, the Netherlands

Introduction

Some endemic diseases are implicitly associated with dairy production. These, so called, production diseases do cause large negative economic effects. Because of the chronic nature of production diseases, economic damage is spread out over the year, and a large part of the economic damage, such as lower milk production are often unnoticed by the dairy farmer. Farm accounting reports give all kinds of detail about the costs of production but these are in terms of feeding costs, machinery costs, and costs for animal improvement. The factor health costs only comprise costs for drugs and the veterinarian, which is only a small proportion of the total economic damage of a production disease. Still economic arguments are often used by farmers not to follow an advice or even to complain about the costs of veterinary service. Without good knowledge about the economics of animal health, these economic arguments are often seen as a burden for the veterinary practitioner. Instead of following good advice, farmers often “just” neglect that advice because they say prevention is too expensive.

A good understanding of the costs of a disease is important to support decisions of farmers with regard to animal health. It is important that this understanding goes beyond averages that are provided in literature. All calculations of costs of disease and cost-effectiveness of preventive and curative measures can be regarded as averages for a certain situation. Costs of diseases vary from farm to farm. This is not only dependent on the incidence of disease but also on the effects of disease on production, culling and mortality and price levels (Halasa et al., 2007). In order to support decisions of farmers, the advisor must be able to interpret such published data to translate them to the specific situation of an individual farm. Therefore, insights in the theories behind economic calculations in the field of animal diseases is necessary. In this contribution, an economic decision making framework will be described.

ANIMAL HEALTH FROM AN ECONOMIC PERSPECTIVE

Factors that Determine the Costs of Disease

The cost factors making up the total costs of disease consist of two big groups: failure costs and preventive costs (Hogeveen et al., 2010). Failure costs are the costs that are associated with the occurrence of the disease. The most obvious failure cost factors are those associated with treatment. Costs for diagnostics, veterinarian and drugs consist of expenditures and are very visible. Extra labour to treat diseased animals and discarded milk and meat are also visible, but it can be more difficult to establish the monetary value of these factors. The second group of failure cost factors are associated with production losses. Production diseases can lead to a decreased milk yield, lagging growth, a decreased product quality, increased mortality and an increased risk of culling. At the cow level, there are trade-offs between treatment and production losses. Better treatment will decrease the production losses. This means that the level of treatment can be optimized (e.g., Down et al., 2013; McArt et al., 2014; Steeneveld et al., 2011). Finally, a high incidence rate of a disease can increase the risk of new cases of disease, either because of infectiousness of diseases (one infected animal can infect another) or because of a reduced immunity due to disease. For instance, in the case of hyperketonaemia, the observed production losses can mainly be attributed to other, following, diseases rather than to the case of hyperketonaemia itself.

The second group of cost factors are associated with prevention. These preventive costs include all preventive measures that are undertaken by the farmer to prevent occurrence of the disease. There is a wide range of possible preventive measures against production diseases. All farmers have implemented more or less preventive measures. These can be structural measures and are associated with the design of the barn and the milking parlour (measures that cannot be changed too easily). Most preventive measures are, however, part of the daily management of a dairy herd. Preventive costs consist of costs of diagnostics, labour costs, veterinary service (e.g., veterinary herd health and management programs), investments and consumables. Moreover, there exists a trade-off between the preventive costs and failure costs. More preventive action will lower the incidence rate of disease and vice versa. More on this relation will be provided later in this chapter.

Although the economic effects of production diseases differ between diseases, farmers and farming systems, and that the value of the cost factors differs between farms and farm systems, the economic principles behind them are the same. In the following sections, failure costs and preventive costs of different production diseases are described in more detail.

Failure Costs of Production Diseases

In an overview paper, Hogeveen and van der Voort (2016) summarized the failure costs of production diseases. Costs of clinical mastitis varied from € 87 to € 1,006 per case, with most estimates being in a range of € 200 - € 400 per case. The differences were due to differences in country, causing pathogens, breed of cattle and production levels. Overall, failure costs of mastitis were estimated to be € 71 and € 108 per cow on the farm per year. In a recent study, the total costs of mastitis were estimated on 109 Dutch dairy farms (data not yet published). On average, half of the total costs of mastitis (€ 240; failure costs plus preventive costs) consisted of preventive costs. However, there is a large variation between farms (Figure 1).

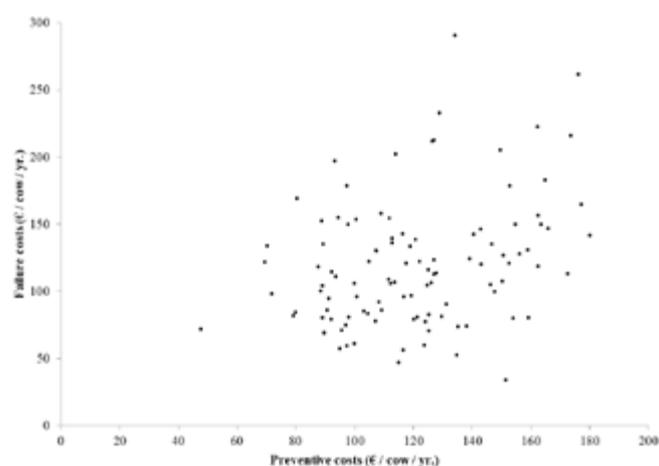

Figure 1. Estimated average preventive and failure costs associated with mastitis (€ per lactating dairy cow per year) per herd. Each point represents an individual dairy farm (n=108).

For lameness, costs per case were estimated to vary between € 111 and € 198 per case, depending on the cause and € 39 and € 124 per cow on the farm.

Recently two papers were published about the costs of subclinical ketosis (hyperketonaemia), leading to estimates of € 257 and € 265 per case. Current estimates of the costs of ketosis are only scarcely available in scientific literature. Costs of ketosis were estimated to vary from US\$78 to US\$289 per case of ketosis.

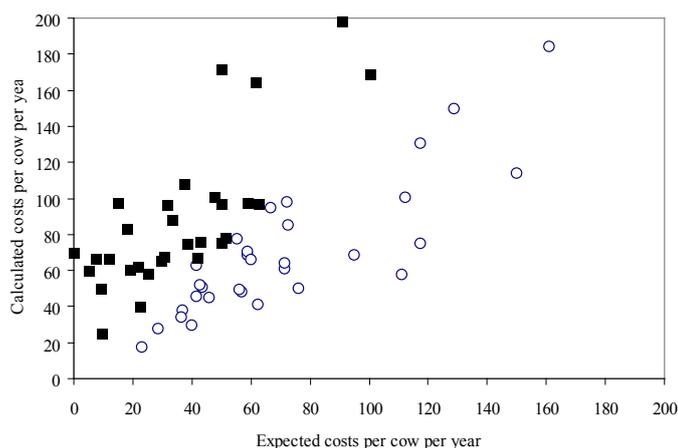

Figure 2. Expected economic losses per cow per year vs the calculated economic losses per cow per year (group 1: "good estimators" (○), and group 2: "under estimators" (■) (Huijps et al., 2008).

Even though there are quite some differences between the estimates, these estimates remain averages for the specific situation (often a standard farm for the region of interest) that was studied. In reality, there are large differences between farms. A study by Huijps et al. (2008) calculated the failure costs of mastitis for individual farms using a straightforward calculation tool. There was a large variation in farm-specific costs of mastitis, from € 17 to € 198 per cow per year (Figure 2). Moreover, before these calculations were made, the farmer gave his own estimate of the costs of mastitis. It appeared that only 8 % of the farmers estimated the failure costs of mastitis correctly. More than half of the farmers underestimated the costs of mastitis with more than 25%.

Since a good estimate of the failure costs of production diseases is a basis for economically sound decision making about preventive measures, it is important that farmers and their advisors do spend time on a proper estimation of the failure costs of production diseases. Quite some tools have been developed to make farm-specific estimations of failure costs of production diseases. Many of these tools are, as part of the extension task of universities, available on-line.

Economic Optimization of Preventive Measures

An economic approach in the selection of preventive measures can be done by looking at the possible preventive measures against production diseases and compare the costs of these preventive measures with the avoided failure costs when they are applied (Hogeveen and van der Voort, 2016). A preventive measure where the avoided failure costs are larger than the additional preventive costs has a positive net-benefit and is thus cost-effective. In such an analysis the following steps have to be taken:

1. Estimate the failure costs of the disease on this farm
2. Define a possible additional preventive measure or strategy that is applicable for this farm's situation
3. Estimate the effect of the preventive measure (e.g., in terms of reduction of incidence of disease)
4. Calculate the costs of implementation of the preventive measure
5. Recalculate the failure costs of the diseases with the expected reduced incidence on this farm
6. Determine the difference between the recalculated failure costs and the initial failure costs. This difference represents the expected benefit of implementation of the preventive measure
7. Compare the additional costs with the expected benefit to evaluate the cost effectivity.

Steps 2-7 may be repeated for additional preventive measures and may include multiple preventive measures (i.e. a disease prevention strategy).

Tool

Within in the EU IMPRO project (www.impro-dairy.eu) a cost-benefit tool has been constructed to support farmers and their advisors to support decisions on preventive measures against production diseases. Basically, the model estimates the total costs of the four common production disorders (Berge and Vertenten, 2014) major management systems, and fresh cow clinical conditions associated with ketosis in western European dairy herds. A total of 131 dairies were enrolled in Germany, France, Italy, the Netherlands, and the United Kingdom during 2011 to 2012. A milk-based test for ketones (Keto-Test; Sanwa Kagaku Kenkyusho Co. Ltd., Nagoya, Japan; distributed by Elanco Animal Health, Antwerp, Belgium: mastitis, lameness, ketosis and metritis). In the cost-benefit module, total costs are defined as the sum of failure costs and preventive costs. It is possible to focus on one disease only or to estimate the costs of several diseases. A note should be made that the model estimates the costs of each disease individually and potential interactions between these diseases are not estimated.

The basic model input for the cost-benefit tool includes:

- Herd characteristics
- Milk production, number of dairy cows
- Herd health characteristics
- Mastitis, lameness, ketosis and metritis
- Price input
- Milk price, feed price, wage, replacement value, slaughter price, penalties, bonuses
- Farm characteristics
- Replacement rate, culling, death

With regard to herd health characteristics, different input is required for each specific disease. Mastitis requires input on the incidence of clinical mastitis and somatic cell count (SCC) classes, in which the first is derived from health recordings (or alternatively farmers' estimates) and the latter is derived from milk recordings. Lameness requires input on lameness scoring, ideally hoof trimming records are used. Alternatively users could estimate the incidence of moderately lame and severely lame animals in which it should be kept in mind that farmers tend to underestimate the severity of lameness (Bruijnis et al., 2010). Ketosis requires input on the fat-protein ration, if fat-protein ration has been larger than 1.5 within the first 100 days in milk the cow is diagnosed with ketosis (Duffield et al., 1997; Krogh et al., 2011). Metritis has been divided into clinical metritis and subclinical metritis, diagnosis of these illnesses has to be performed by the farmer according to predefined definitions. Clinical metritis is defined as: an animal that is not systematically ill, but has an abnormally enlarged uterus and a purulent discharge detectable in the vagina, within 21 days post-partum. Clinical endometritis is defined as: the presence of purulent (>50% pus) uterine discharge detectable in the vagina 21 days or more after parturition, or mucopurulent (approximately 50% pus, 50% mucus) discharge detectable in the vagina after 26 days post-partum (Sheldon et al., 2006) and pathogenic bacteria often persist, causing uterine disease, a key cause of infertility in cattle. However, the definition or characterization of uterine disease frequently lacks precision or varies among research groups. The aim of the present paper was to provide clear clinical definitions of uterine disease that researchers could adopt. Puerperal metritis should be defined as an animal with an abnormally enlarged uterus and a fetid watery red-brown uterine discharge, associated with signs of systemic illness (decreased milk yield, dullness or other signs of toxemia).

Specific price input is requested from the user, however if a user is not sure about his input, default, country specific, values can be used. The most influential price input are requested: milk price, feed price, labour costs, replacement value of a dairy cow, costs of destruction, slaughter price, penalties paid and bonuses received as a consequence of an elevated/ low SCC.

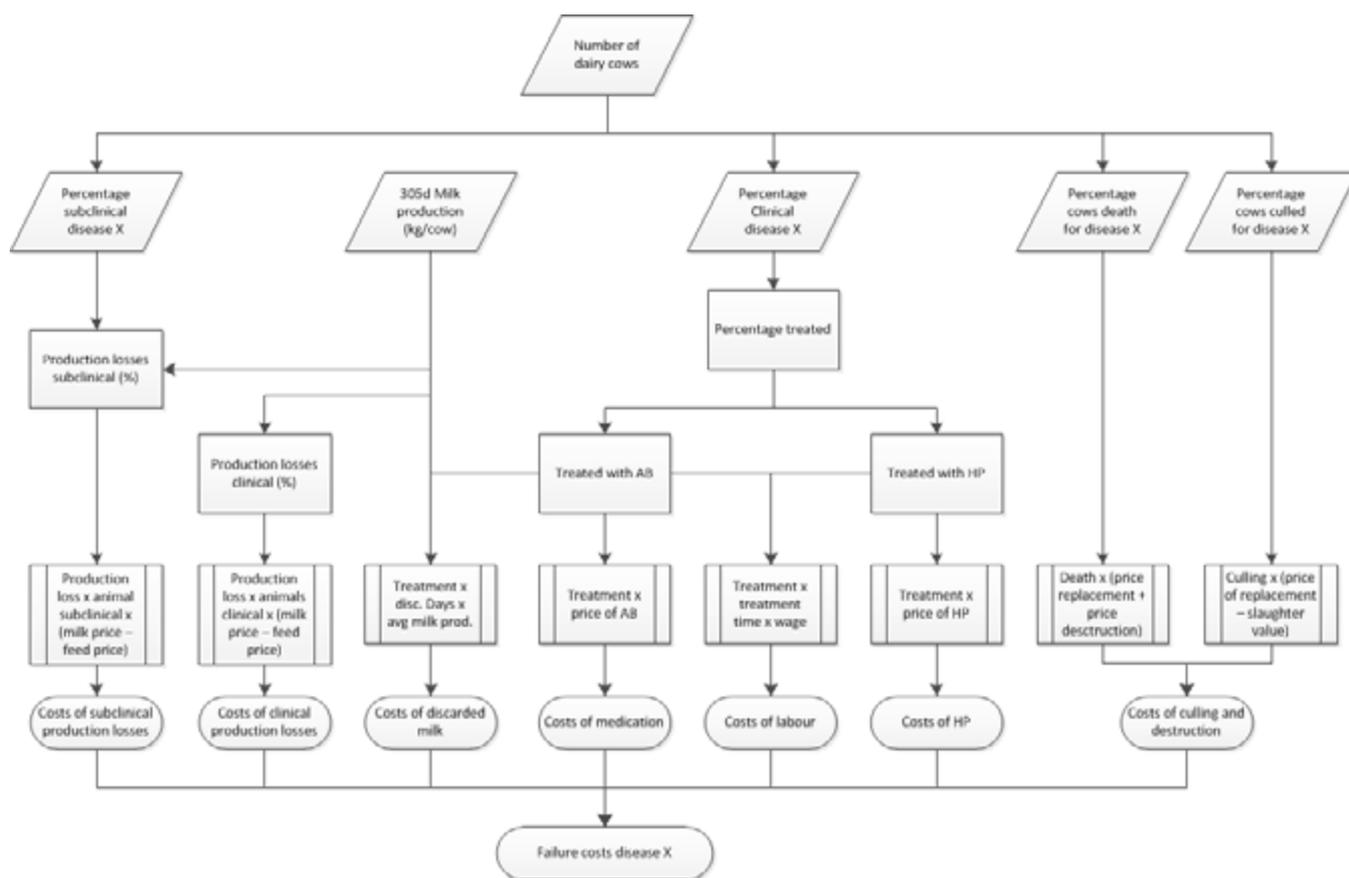

Figure 3 General structure of the calculation of failure costs. Input is requested at the parallelogram, technical assumptions are made in the squares and economic assumptions and calculations are made at the squares within a square, partial costs are derived at the pill shaped boxes, each path should be followed to estimate the total failure costs of a disease.

When all input data has been collected the users have to decide which preventive strategy they would like to implement on the farm. If these desired measure(s) is/are not included it/they can be manually added to the set of measures (up to 3 measures). Given the selected measures veterinary advisors/ farmers have to decide what the impact of the measures will be on animal health characteristics of the herd. E.g. if measure x is implemented on the farm by how much will it reduce disease y. The cost-benefit tool does not give any reference values of the expected effect of the chosen management measures. If the farmer is the user, it is advised he/ she consults the veterinary advisor on this topic.

As a first step, failure costs are calculated based on the general structure given in Figure 3. Failure costs generally consist of costs of (sub)clinical production losses, discarded milk, medication, labour, treatment, culling and destruction. Next, for each disorder at least 9 measures were derived from literature and/or expert knowledge and costs were estimated. The costs of each of these management measures consist of three distinct cost factors:

- **Labour**, costs of labour associated with performing the measure.
- **Consumables**, costs of material necessary to complete the measure
- **Investments**, costs of investments that are generally present on the farm for longer than one year

Using these factors default costs for each of these measures are calculated. Also expected effects of the preventive measures are built in the tool. Given the expected effect the model estimates current failure costs, potential reduced failure costs (after implementation of the selected measure) and potential increased preventive costs (after implementation of the selected measure). The difference between the current failure costs and potential total costs (reduced failure costs plus increased preventive costs) is the net effect of the management measures on farm income.

Besides the provided preventive measures, the user can define new preventive measures. Moreover, the user can change all assumptions that have been made and can thus adjust cost factors and effectivity of preventive measures to reflect the specific farm situation as good as possible.

Conclusions and Implications

On a dairy farm, production diseases are responsible for a considerable proportion of the costs of milk production. These costs consist of failure costs and prevention costs. The failure costs of production diseases are only for a part visible to the dairy farmer. Farmers tend to underestimate the failure costs of production diseases. Farm-specific calculation of the costs of production diseases is therefore necessary as a starting point to discuss potential preventive measures.

Because of the large variation in failure costs of production diseases between farms, there is room for investment in preventive measures. The net benefits of preventive measures should be calculated for a farm specific situation. A tool has been described and will be available on-line that can be used to calculate the net effect of a wide range of potential preventive measures.

Good knowledge of the economics of production diseases including ways to support farmers with economically founded advises to prevent production diseases may be a key to turn economics from a burden towards a blessing for the veterinary practitioner.

Natural Treatments for Mastitis and Infertility

Hubert Karreman

VMD, PO Box 6, Saxapahaw, North Carolina, USA 27340

Background

Since 2002, certified organic animals in the United States that are given antibiotics or hormones must be permanently removed from the organic sector (7CFR205.238c7)¹. Many skeptics believe that this reduces animal welfare. However, it cannot be stated strongly enough that the use of antibiotics on their own does not constitute animal welfare. Animal welfare is much broader – it includes how the animals experience life on the farm. In relation to reduction of antibiotic use, there is reason to believe that the United States certified organic livestock sector is leading the way globally in developing alternatives to antibiotic use and reducing antibiotic use in animal agriculture in general.

Over the course of the last 15 years, there have been epidemiologic studies that compare conventional herds to organic herds. The author was involved with two of studies that compared standard production and reproduction parameters which were conducted among dairy cattle herds in the Lancaster, Pennsylvania region using standardized data from Dairy Herd Improvement Association.

In 2006, data was analyzed from more than 30 herds in Lancaster, PA. The herds were matched for breed, herd size and located within one mile from each other. (Table 1 and Table 2)

Similar results were found in study conducted in 2016 with more than 60 herds in Lancaster, PA. The herds were once again matched for breed and herd size but in this case were located within the same postal zip code. Each postal zip code area generally encompasses about 5-10 square miles of the total 980 square miles that Lancaster County comprises. (Table 3 and Table 4)

The results of 2016 milk production comparison shows the only significant differences to be yearly herd production level and the somatic cell count scores. While conventional production had significantly better somatic cell count scores, both groups had a linear somatic cell count score below <100,000 (linear SCC 3), well below the generally accepted standard for good quality milk of somatic cell count of 400,000 (linear SCC 5).

With the above results it would be good to describe the treatments that the organic herds are using for common maladies such as mastitis and infertility. The data shown for certified organic herds includes only animals that are in the herd. No animals treated with antibiotics and/or hormones are in the certified organic data set presented above.

Mastitis

With prohibitions on antibiotics and hormones, it is imperative to rely on the animals' immune systems rather than antibiotics. Three important components will determine immune response to challenges. First is the animal's genetic resistance or susceptibility to specific pathogens. Secondly, when the diet is complementary to the animal's digestive system, the immune system will be able to respond efficiently. Thirdly, stimulation and modulation of the immune system is critical to regain health. In addition to genetics, diet and immune enhancement, the following factors generally ensure a healthy animal: (1) clean, dry bedding (2) fresh air and proper ventilation, (3) plenty of high quality water, and (4) direct contact with pasture/earth. The author has found that dairy cattle given pasture and high forage diets tend to have dramatically fewer health issues than those confined to concrete and fed diets heavy with grains to maximize production. The author's experience as a clinical practitioner bears out the same results in regards to dramatically less systemic illness in herds that utilize management-intensive grazing during the growing season, feed high forage diets throughout the year, and provide dry bedding and fresh air.

The use of biologics, botanicals and anti-oxidants are rational approaches to utilize when not using antibiotics and hormones. When considering human medicine and veterinary medicine, biologics and botanicals were relied upon prior to the advent of antibiotics and synthetic hormones. Vaccines can also be an important factor in helping the immune system respond rapidly to viral and bacterial challenges that may arise during an animal's life.

Biologics are compounds derived from living materials such as soil, plants, animals, fungi, bacteria and viruses. Products derived from these sources can affect both the non-specific and specific branches of the immune system. Products which affect the non-specific, or innate, immune system generally increase activity of interferon, which then stimulates natural killer cells and macrophages, which non-selectively kill pathogens. Passive antibodies, such as IgG antibodies which are created by a donor animal and then administered to a recipient animal, quickly target and efficiently eliminate pathogens in highly specific ways. Vaccines, the most ubiquitous biologics, stimulate the recipient to create antibodies in a preventive manner so that a rapid response is mounted by the animal when challenged by the pathogens for which it was vaccinated. In the author's experience, animals with coliform mastitis respond well if antibodies are administered within 12 hours of the onset of symptoms.

Conditions such as localized mastitis (not systemic coliform mastitis) and elevated somatic cell counts need to take into account milking hygiene and technique prior to considering treatment. This holds true for both conventional systems that use antibiotics as well as organic systems which prohibit antibiotic usage. While spontaneous self-cure can occur (depending on extent of challenge and immune capability of the animal) there are non-antibiotic treatments which appear to effectively resolve the problem quickly. Utilizing biologics is one method. While there are commercial vaccines available to effectively prevent and/or reduce severity of coliform mastitis symptoms, commercial vaccines for other types of mastitis aren't as common. For mastitis pathogens including staph and strep, an autogenous vaccine created directly from the milk of the specific herd is possible and in the author's experience has worked well in herds with a Staph aureus problem, if closely adhering to the vaccine program protocol, which starts at 6 months of age, and administering boosters at various times throughout the life of the animal. Other biologics include products derived from the colostrum of specifically stimulated, immunologically mature animals. This is a rational approach since colostrum is rich in antibodies. Biological products used against mastitis are generally injected subcutaneously and may help to stimulate IgA. This is smart since IgA is known as an antibody type that monitors mucosal membranes.

Botanical medicines are also available for mastitis to replace antibiotics. For instance, there are many commercially available topical ointments and sprays which can be applied to cows' udders against mastitis. Many popular ointments that are anti-inflammatory and soothing to a swollen udder contain Japanese peppermint mint (*Mentha japonica* and/or other mentha species). Farmers often use these as a first line of defense when milk quality is of concern. There is widespread testimonial and anecdotal evidence regarding such ointments. Since the teat orifice of a cow is very easy to infuse with medication, dairy farmers (both organic and conventional) will often infuse treatments other than antibiotics for mastitis. Using non-antibiotic treatments is becoming more common and popular due to highly sensitive tests that can pick up minute traces of antibiotics in milk and result in significant penalties to a farmer. North Carolina State University has done clinical trials with commercially available botanical infusions. A multi-ingredient botanical product called Phyto-Mast™ has been studied extensively. The active ingredient is thymol, balanced with angelica, gaultheria, and glycyrrhiza, in a base of organic olive oil. In an in vitro study done on its ingredients and their effect on pathogens, it was shown that thymol at a concentration of greater than 2% consistently resulted in no bacterial growth of Staph. aureus, Staph. chromogenes, and Strep. uberis.⁴ In a study with lactating

cows, it was shown that treatment with the botanical preparation Phyto-Mast™ resulted in a reduction of the time to clinical recovery.⁵ In a study on drying off cows, the efficacy was similar to that of conventional (antibiotic) therapy, and there were no apparent adverse effects.⁶ As part of a PhD thesis (but not published in a peer-reviewed journal), it was shown that Phyto-Mast™ used in combination with Orbeseal™ had nearly identical cure and prevention of intramammary infections as published information with Quartermaster™ used in combination with Orbeseal™ (78% and 80%, respectively). Regarding the all-important issue of residues for food safety concerns, Phyto-Mast™ was detectable and quantifiable in goat plasma beginning with the 15-minute post treatment sample, but was no longer detectable in the 4-hour post treatment sample. Thymol residues were only detected in the 12-hour post treatment milk sample. An inflammatory response was not evident following phytoceutical administration.⁷ There is a 3 year USDA-funded study currently being done at North Carolina State University to describe the pharmacokinetics of three botanical products in lactating dairy cows: intramammary administration of Phyto-Mast™, an orally administered garlic tincture and a topically applied oregano oil. Garlic and oregano oil are very commonly used for illness in the organic dairy sector. When considering the current literature, Phyto-Mast™ is possibly the most scientifically studied natural treatment known.

Homeopathic remedies are another mode of treatment utilized on many organic farms. The author's experience as a herdsman treating organic dairy cows with homeopathic remedies was so successful that he went on to learn veterinary medicine in order to understand how such dilute remedies work. It quickly became evident that the immune system was involved. Homeopathic prescribing generally dictates that whatever symptoms a material in crude form can elicit, its derivative in highly diluted and vigorously shaken form can cure when a patient is ill and showing those same symptoms (the axiom of like cures like). While there are hardly any clinical studies with homeopathic remedies in dairy cows, there are simply too many anecdotal successes to dismiss this mode of therapy entirely. In fact, many of the herds in the Lancaster, Pennsylvania region that are included in the data presented in this paper rely on homeopathic remedies to some degree for milk quality concerns and fertility issues.

Some commonly used homeopathic remedies for high somatic cell count and clinical mastitis include apis, belladonna, bryonia, calc carb, calc phos, hepar sulph, lachesis, phytolacca, pulsatilla, silica, and sulfur. These medicines are commercially available as tiny medicated pellets and administered two to three times a day upon any mucosal membrane, usually given orally but also given vaginally. Homeopathic remedies can also be administered as liquids or sprays. A key concept when using homeopathic remedies is that selection of remedy is highly specific to the symptoms shown and that one needs to change remedies if symptoms change. When a clinical cure is observed, the need for remedy administration ceases. For instance, if a cow is exhibiting signs of mastitis with a hot, swollen, red udder and also has a pounding heart, dry oral membranes, and dilated pupils, homeopathic belladonna would be indicated and given hourly until those symptoms subside and/or change. (The crude form of *Atropa belladonna* if ingested would result in those same symptoms). In the author's experience, farmers that enjoy using homeopathic remedies tend to be extremely observant to subtle changes in the condition of their cows. When using standard antibiotic therapy, administration of the medicine requires a set amount of days in order to ensure adequate time to eliminate the bacterial pathogen challenge and observations of subtle changes are not necessary. Like many other natural treatments, homeopathy relies completely on enhancing the animal's own immune system to eliminate the infection whereas the primary aim of antibiotic therapy is only to eliminate pathogens.

An interesting hybrid approach to the biological and homeopathic methods is to make an autogenous vaccination by extracting the animal's own blood, quickly mixing in a specific homeopathic remedy, and re-injecting the mixture subcutaneously to the same animal. This method is

Table 3: Comparison of production between conventional and certified organic herds (2016)³

Variable	Conventional	Organic	P value
Conception Rate (n=59)	47.2	49.2	.55
Pregnancy Rate (n=59)	18.6	18.6	.55
Percent Observed Heats (n=59)	41.7	31.2	<.01
Days to 1 st service (n=67)	87	47	<.01
Days open (n=67)	143	101	<.01
Calving Interval (n=67)	13.5	13.4	.43
Cull rate (involuntary) (n=65)	26.9	24.8	.27
Avg. age (n=65)	47.5	49.7	.10

Table 4: Comparison of reproduction between conventional and certified organic herds (2016)³

called an autosanguis, a therapeutic procedure utilized by practitioners of homotoxicology, a derivative of homeopathy which applies a broad range of homeopathic remedies in various potencies to affect physiologic processes. A commercial example of a homotoxicologic product which is known around the world is Traumeel™ (Heel GmbH). Though not traceable through titer changes, correctly selected homeopathic remedies appear to resolve various conditions, if only ascertained through individual clinical cure. No doubt some portion of the data presented for certified organic farms is associated with homeopathic remedies being utilized.

Reproduction

The results of the most recent study (2016) shows the only significant differences are in observed heats, days to 1st service and days open. While the organic herds had significantly better levels in these three categories, the results may be due to more use of bulls rather than artificial insemination. The data presented in the tables show that while there are some significant differences at the herd level between reproduction parameters of conventional and certified organic herds, there are also no differences in key reproduction indicators. One key indicator where there are no significant differences is pregnancy rate. In the United States, there is widespread use of synchronized artificial insemination using protocols involving multiple injections of prostaglandin $F_{2\alpha}$ and gonadorelin (PG) releasing hormone (GnRH). These two hormone compounds are prohibited from use in certified organic livestock in the United States. Aside from the use of more bulls to reduce days to 1st service and days open while reducing observed heats, it is intriguing to look at modes of treatment for reproduction and fertility issues in certified organic herds. Certainly the first two weeks post-partum are critical to make sure the uterine environment will be ready for timely conception. In cases of metritis, placement of antiseptics is needed starting about day 3 post-partum until the cervix closes. Manual removal of placenta at approximately day 5 or 6 post-partum is critical. Antiseptic compounds such as iodine (1 gram dry or equivalent in liquid volume) are beneficial if given daily before the cervix closes. Other products include essential oils (mixed within powder and placed in capsules), colostrum-whey infusions mixed with botanicals such as calendula tincture, aloe lavages, and dilute chlorhexidine. The key is to make sure that there is daily treatment prior to the cervix closing. Oral administration of homeopathic pyrogenium is often utilized. In fact pyrogenium is derived from rotten meat, which is what a retained placenta is; thus, pyrogenium is a perfect homeopathic match for the condition of retained placenta. In treating pyometra, infusing the uterus with a mixture of 3 parts of dextrose or 3 parts of hypertonic saline with 1 part 7% iodine tincture has helped to clear many low grade pyometra cases if treated within the first 3-4 months post-partum. The volume infused is based on the size of the pyometra. For instance a pyometra that is the size of a 60 day pregnancy would be treated one time with 60 cc of the mixture. Whereas a pyometra that is the size of a 90 day pregnancy is treated with 90cc of the mixture two times one week apart. A 120 day "pregnancy" is best treated with 120cc twice weekly for 2-3 weeks. Larger pyometra is often not responsive to treatment.

Cows that are physiologically normal but aren't showing behavioral estrus are prompted into behavioral estrus with a powdered botanical phyto-estrogenic combination of *Angelica sinensis*, *Turnera diffusa*, *Oenothera biennis*, *Dioscorea villosa*, *Mitchella repens*, *Viburnum opulus*, *Linum usitatissimum*. The combination is given orally beginning at mid-cycle and given daily for six days in a row or until heat, whichever is first. Though no data exists for this use, the author's clinical impression is that this treatment brings correctly selected cows into behavioral estrus >80% of the time. Cows do not abort if given this treatment by mistake, as it is phyto-estrogenic and not luteolytic. Consequently this herbal combination is not effective for treatment of pyometra as is PG.

Conclusion

The need to look more closely at non-antibiotic and non-hormonal therapy as a primary mode of treatment has been stimulated by the "no antibiotics" rule in the United States certified organic livestock sector. Epidemiologic cross-sectional studies can give clues as to what may be working even though specific cause and effect studies are lacking. Further clinical studies are needed to provide the data necessary to help reduce antibiotic use in livestock agriculture.

Keywords: Ultrasonography, Radiology, CT, MRI, Endoscopy, Infrared thermography, Cattle

Introduction

Diagnostic imaging procedures such as ultrasonography, radiography, computed tomography (CT), magnetic resonance imaging (MRI), endoscopy and infrared thermography have become widely used in bovine medicine in the past decades particularly in veterinary teaching hospitals. However, CT and MRI are still limited to well-equipped institutions because of their high costs and the necessity to use general anesthesia (Nuss et al., 2011c). Furthermore, a radiographic unit is not standard equipment for bovine practitioners (Kofler et al., 2014). The same conditions apply for the use of endoscopes, even though teat endoscopes are used routinely in specialized practices (Geishauser et al., 2005).

Non-invasive ultrasonography, on the contrary, evolved into a valuable diagnostic imaging technique in almost all fields of bovine medicine (Table 1, 2). This is most probably due to the development of technically improved, cost effective portable units allowing its use at any given location (King, 2006).

The first goal of this presentation is to review the various technical opportunities of diagnostic imaging, the second goal is to point out the wide range of applications of ultrasonography in bovine practice using commonly available units equipped with 5 – 8 MHz rectal probes. We would like to encourage veterinarians to use diagnostic ultrasound for various other indications beyond the examination of the reproductive tract.

Preceding clinical examination

A careful physical, gynecological/andrological, orthopedic, and neurological examination of the patient is always the first step in making a clinical diagnosis before imaging techniques are used to achieve a definite diagnosis (Baumgartner, 2014). This thorough clinical examination reveals the “organ/region of interest” for the subsequently applied diagnostic imaging technique (Kofler & Hittmair, 2006).

Ultrasonography

Ultrasonography has been globally established as a routinely applied diagnostic imaging method in bovines. The female reproductive tract was the first organ system studied by ultrasound and this application became widespread in ambulatory practice (Pierson & Ginther, 1988; DesCôteaux et al., 2009; Mee et al., 2009; Fricke et al., 2016). Nowadays, ultrasound is an integral part of diagnostics in gynecology, andrology, internal medicine, cardiology, orthopedics and neurology in many veterinary teaching hospitals (King, 2006). The person undertaking the clinical evaluation usually also performs the ultrasonographic investigation. The advantage of this union is that the operator is well informed about the anatomical sites in question and is therefore able to relate these to the previously determined clinical findings (Scott, 2008, 2009).

Making a definite clinical diagnosis with abdominal, thoracic, cardiac, umbilical, urogenital, gynecological and musculoskeletal disorders is often challenging or impossible. Ultrasound is superior to radiography for the diagnosis of conditions affecting soft tissues (Table 2). It is ideal

for the evaluation of musculoskeletal disorders and other swellings (Kofler, 1996a,b; Nuss & Maierl, 2000; Nuss, 2003; Nuss et al., 2007, 2011a; Altenbrunner-Martinek et al., 2007; Kofler & Altenbrunner-Martinek, 2008; Gansohr et al., 2009). Even bone surfaces that are difficult to assess radiographically such as the scapula, ribs and pelvis, as well as the bones of the limbs can be imaged ultrasonographically for the presence of fractures, osteitis and osteomyelitis (Kofler, 1997a,b; Grubelnik et al., 2002; Kofler et al., 2014).

Ultrasonographic examinations should adhere to a standardized protocol (Kofler & Hittmair, 2006; Braun, 2009a-c; Ollivett & Buczinski, 2016). With whose assistance, the sonographer examines the organ/structure of interest in a certain sequence in order not to overlook lesions or conditions. Additionally, each organ should be imaged in transverse and longitudinal views (O'Brien & Forrest, 2005; Buczinski, 2009b).

The ultrasound probe is used by the sonographer much like the own fingers for sonopalpation (Kofler & Hittmair, 2006) examining the contents of body and synovial cavities, cysts, vessels or other fluid-filled lesions for the presence of liquid, semi-solid, or solid contents and/or inflammatory effusion. Flow phenomena are tested by applying forced pressure to a body cavity showing effusion with either the transducer or the contralateral hand and verifying flows on the monitor image (Kofler & Hittmair, 2006).

In addition, sonopalpation is employed for the diagnosis of thrombus formation and differentiation of arteries and veins. Normal veins can be compressed with the transducer and pulsed flow is identified in arteries (Kofler, 1995a; Braun & Forster, 2012; Braun et al., 2013). The main vascular diseases in cattle include inflammation of the vessel walls, thrombosis, and aneurysm (Kofler et al., 1996, 2002; Bollwein et al., 2000; Braun & Föhn, 2005; Buczinski, 2009a). Colour Doppler sonography had been established as a useful technique for the investigation of the genital blood flow during all reproductive phases (Herzog & Bollwein, 2007; Krueger et al., 2009; Waldvogel & Bleul, 2014; Heppelmann et al., 2013; Bollwein et al., 2016).

Centesis of body and synovial cavities, puncture of the subarachnoid space, biopsy of organs for cytologic and/or histologic analysis and transvaginal puncture of ovarian follicles is frequently applied (Heppelmann et al., 2013, 2015; Braun, 2016a; Braun & Attiger, 2016). Following ultrasonographic assessment of the designated structure, it offers guidance for the needle placement, assisting with the measurement of the distance from the skin surface to the structure. This is especially important if a freehand or an ultrasound-guided needle placement is performed (King, 2006; Braun et al., 2009a,b; Tharwat et al., 2012; Braun, 2016a). A new clinical application is the ultrasound-guided perineural anesthesia of proximal limb nerves (femoral, sciatic, paravertebral nerves, brachial plexus) as an alternative to general anesthesia (Iwamoto et al., 2012; Shokry & Berbish, 2012; De Vlamynck et al., 2013; Kramer et al., 2014; Re et al., 2014, 2016). Furthermore, 6–10 MHz linear transducers had been applied as a useful ancillary tool for assessing spinal cord diseases (Testoni et al., 2010a,b; 2012, 2014; Braun & Attiger, 2016).

The costs for purchase and up-keep of a sonographic unit is just too high to limit its application to the bovine reproductive tract. In calves in particular, nearly all organ systems can be examined with 5 – 8 MHz rectal linear probes (Table 1, 2), and even in cows these rectal probes can be used for imaging of pathologies of many joints, the teat, pleura and the lung, the reticulum (mainly in young cattle), umbilical region, large vessels and for determination of the back fat thickness (Cartee et al., 1986; Lischer & Steiner, 1994; Kofler & Edinger, 1995; Braun et al., 1997; Rabeling et al., 1998; Flöck, 2003, 2004; Klein et al., 2005; O'Brien & Forrest, 2005; Flöck & Winter, 2006; Joshi & Herdt, 2009; Rings, 2009; Steiner & Lejeune, 2009; Hussein et al., 2013; Buczinski et al., 2013, 2014; Braun, 2016b; Ollivett & Buczinski, 2016).

The issue of the Veterinary Clinics Food Animal from 2009 entitled “Bovine Ultrasound” (Fig. 1) covers the examination technique and the

ultrasonographic findings of the gastrointestinal tract, liver, umbilical region, the cardiovascular, respiratory and musculoskeletal system, urinary tract, udder and teat, the female and male reproductive tract (Braun, 2009a,b; Buczinski, 2009a,b; Babkine & Blond, 2009; Flöck, 2009; Franz et al., 2009; DesCôteaux et al., 2009; Gnemmi & Lefebvre, 2009; Steiner & Lejeune, 2009; Kofler, 2009). This issue and the recently published issue entitled "Update on Ruminant Ultrasound" (Fig. 2) are highly recommended as helpful guides for clinicians interested to expand their diagnostic horizons (Ollivett & Buczinski, 2016; Mitchell & Schwarzwald, 2016; Braun, 2016a,b; Bernier Gosselin et al., 2016; Re et al., 2016; Bollwein et al., 2016; Fricke et al., 2016).

Many journal articles also give an overview of the ultrasonographic examination and the pathologies of the musculoskeletal system (Kofler, 2009, 2011; Kofler et al., 2014), the sole horn and the digital fat pad thickness (Kofler et al., 1999; Bicalho et al., 2009), the reproductive tract and mammary gland (DesCôteaux & Buczinski, 2009), pathologies of the retropharyngeal region (Braun et al., 1994; Gansohr et al., 2009; Rings, 2009), heart and pericardium (Flöck & Baumgartner, 2001; Braun et al., 2001; 2007a; Braun, 2009c; Buczinski et al., 2010), lungs (Braun et al., 1997; Rabeling et al., 1998; Jung & Bostedt, 2004; Scott, 2009, 2012, 2013b; Buczinski et al., 2013, 2014), gastrointestinal tract (Braun, 1997, 2003; Braun et al., 2007c; Braun & Feller, 2008; Braun et al., 2008a, 2010, 2011; Kumar & Saini, 2011; Braun & Gautschi, 2013), liver and spleen (Nagaraja & Lechtenberg, 2007; Braun & Krüger, 2013; Scott, 2013a; Abdelaal et al., 2014), kidneys (Braun et al., 2008b; Abdelaal & Flöck, 2015), pancreas (Tharwat et al., 2013) and the abdominal fat necrosis (Tharwat & Buczinski, 2012).

Radiography

During the last half century radiography has been established as a standard diagnostic procedure in bovine medicine. Nevertheless, up to now it has not become a routine procedure in bovine practice, particularly due to the high investments and the rather low frequency of application in practice (Kofler et al., 2014). Until now, only few textbooks and articles have been published about radiography such as these two references: the textbook of "Bovine Radiology" by Bargai et al. (1989) and the recently published DVD "Bovine Radiology – Digital Diagnostic Atlas" from the Vetsuisse-Faculty in Berne (Fig. 3; Steiner et al., 2010). A detailed overview about radiography and ultrasonography in bovine orthopedics was given by Kofler et al. (2014).

Radiography remains the method of choice to image bony structures and the location and type of abnormal masses (Table 1). However, any radiological examination must yield a benefit sufficient to justify the risks of the radiation exposure (Steiner et al., 2010; Kofler et al., 2014).

One of the most frequent indications for bovine radiography (Table 1) is the definite fracture diagnosis, because the type of surgical treatment is mainly based on the fracture configuration (Steiner et al., 1993; Bellon & Mulon, 2011; Nuss et al., 2011b; Wenzinger et al., 2012; Vogel & Anderson, 2014). Other important indications are the diagnosis of luxation, osteitis, osteomyelitis and advanced stages of septic arthritis (Van Huffel et al., 1989; Verschooten et al., 2000; Starke et al., 2006, 2007; Braun et al., 2009a; Desrochers & Francoz, 2014; Kofler & Peterbauer, 2014) and the diagnosis of vertebral column disorders (Zani et al., 2008; Muggli et al., 2011).

The use of radiography for the diagnosis of lung disorders and for traumatic reticuloperitonitis in young and adult cattle which had been used frequently in the past is used rather rarely today (Verschooten et al., 1974; Bellavance et al., 2010; Siegrist & Geisbühler, 2011), while nowadays it had been widely supplemented or replaced by ultrasonography (Babkine & Blond, 2009; Braun, 2009c; Buczinski et al., 2010).

CT and MRI

Computer tomography (CT) is a specific, computerized type of X-ray examination. The most important advantage of CT versus conventional radiography is that CT provides sectional images of body regions without being obscured by overlaying structures (Nuss et al., 2011c). One main benefit of Magnetic resonance imaging (MRI) versus CT is the much more detailed contrast imaging of soft tissues (Zani et al., 2008; Wuersch et al., 2009). Nevertheless the high costs, these imaging techniques can be an option in highly valuable cattle (Steiner, 2012) for achieving a comprehensive diagnosis, which cannot be made by radiography and ultrasonography, and for preoperative planning of a complex surgical intervention (Nuss et al., 2011c; Sparks et al., 2014). However, technical restrictions such as the size of gantry aperture of the CT and the MRI units limit the applications in adult cattle to the examination of the head, cranial parts of the neck and the limbs (Ehlert et al., 2011; Nuss et al., 2011c). In contrary, in calves depending on their size and age the entire body can be scanned (Braun et al., 2014a-c; Ohlerth et al., 2014).

Indications for the use of CT and MRI have been reported and include mainly anatomical studies of bovine limbs (Tiefenthaler, 1997; Schwarze, 1998; Kofler et al., 1999; Ehlert et al., 2011; Raji et al., 2008; 2009; El-Shafey & Sayed-Ahmed, 2012; Tsuka et al., 2012, 2014) and the development of stomach in calves (Flor et al., 2012). Only rarely clinical applications of these methods were reported such as the evaluation of head disorders such as tympanic bulla in calves with otitis-media (Finnen et al., 2011; Lee et al., 2011; Bernier Gosselin et al., 2012), dental, nasal and sinusoidal diseases (Nuss et al., 2011c), atrophic rhinitis (Frame et al., 2000), actinomycosis (Mohamed et al., 2011), brain and spinal epidural abscesses, multiple pulmonary and pharyngeal abscesses and hydrocephalus in calves (Zani et al., 2008; Lee et al., 2009, 2011), nasal osteoma (Wuersch et al., 2009), orthopedic diseases and congenital malformations (Willemsen & Dik, 1995; Lee et al., 2009). Recently a research group from Switzerland established CT reference values of the thoracic and abdominal organs in calves from birth to 105 days of age (Ohlerth et al., 2014; Braun et al., 2014a-c). Table 1 gives an overview of reported indications for CT and MRI in bovines.

Endoscopy

Endoscopic techniques are minimally invasive, and they can be applied in many cases in the standing and restrained animal requiring sedation and local anesthesia depending on the region (Franz, 2012). The direct visualization of inner organ surfaces allows the immediate identification of pathologies, and thus to state a definite diagnosis and to give a substantiated prognosis in many patients (Anderson et al., 1993, 1994; Franz et al., 2004; Franz, 2011; Mann et al., 2013).

Table 1 gives an overview of the most important indications for endoscopy in bovines. Parts of the upper respiratory tract including nasopharynx, larynx, trachea and the two main bronchi (Kahl & Hofmann, 1985; Pringle et al., 1988; Anderson et al., 1994; Dadak et al. 2009; Gansohr et al., 2009; Sydlar et al., 2013; Prohl et al., 2014), the oesophagus (Franz & Baumgartner, 2002; Franz et al., 2006b; Mann et al., 2013), parts of the gastrointestinal tract (Anderson et al., 1993; Steiner & Zulauf, 1999; Klein et al., 2002), the urethra and urinary bladder (Franz et al., 2004; Braun et al., 2007b, 2009b; Chiesa et al., 2009), the abdomen (Wilson & Ferguson, 1984; Rommel et al., 1990; Anderson et al., 1993; Franz et al., 2000), the teat (Medl et al., 1994; Seeh & Hospes, 1998; Sheakespeare, 1998) and the epidural canal (epiduroscopy) (Franz et al., 2008) are all accessible by means of endoscopy. In contrast, rumenoscopia, hysteroscopy and epiduroscopy are to date only of experimental interest (Franz et al., 2006a; Madoz et al., 2010; Franz, 2012).

Theloscopy represents the "gold standard" for direct visualization of the teat canal, the rosette of Fürstenberg, and the teat cistern (Hospes & Seeh, 1999), and is combined with the subsequent surgical intervention in cases of disturbance of milk flow, since mucosal tissue can be removed under visual control in specialized bovine practices too (Medl

et al., 1994; Hirsbrunner et al., 2001; Geishauser et al., 2005).

A further indication for endoscopy is the visually-aided biopsy collection from the liver, abdominal lymph nodes, spleen, kidneys, intestine (Naoi et al., 1985; Klein et al., 2002; Chiesa et al., 2009) and the extraction of fluid samples as described for the bronchoalveolar lavage (Prohl et al., 2014).

Therapeutic applications for endoscopy in cattle are arthroscopy and tenovaginoscopy (Gaughan, 1996; Bertagnoli et al., 2012; Lardé & Nichols, 2014). Another important field for therapeutic endoscopy is the treatment of left displaced abomasum by repositioning and fixation to the abdominal wall under endoscopic control (Newman et al., 2008; Wittek et al., 2009). A comprehensive and detailed overview regarding the examination technique, normal and pathological findings in bovine endoscopy is available online by the Digital Atlas of endoscopy in cattle (Fig. 4) (Schlup et al., 2010).

Infrared thermography (IRT)

IRT has been introduced recently in bovine medicine to identify and determine thermal abnormalities by characterizing an increase or decrease in the surface temperature of their skin at an individual and herd level (Wood et al., 2015). Changes in blood flow can be used to detect inflammation or injuries associated with conditions such as subclinical and clinical mastitis (Hovinen et al., 2008; Polat et al., 2010; Metzner et al., 2014, 2015), to detect lameness early (Alsaad et al., 2015) and to identify foot lesions (Alsaad & Büscher, 2012; Stokes et al., 2012; Alsaad et al., 2014; Wilhelm et al., 2015). Further new applications intended to develop algorithms for assessing the ability of an IRT device for estrus detection and as a predictor of time of ovulation in cows (Talukder et al., 2014), to assess seasonal effects of the environment on semen quality in bulls (Menegassi et al., 2015), and to use IRT for automated detection of bovine respiratory disease onset in receiver calves (Schaefer et al., 2012) (Table 1). However, this technique is highly subjected to environmental thermal artefacts (wind, humidity, exposure to light), so that a controlled environment is a strict precondition before image scanning (Wood et al., 2015). Until now none of these described indications has been established as a routine examination procedure in cattle.

Conclusions

In combination with the assessed clinical findings diagnostic imaging techniques are of great importance for making an exact diagnosis. In some countries, bovine practitioners can refer bovine patients to veterinary teaching hospitals. However, many practitioners use rectal ultrasonographic units for the examination of the reproductive tract, and these 5–8 MHz linear probes are in addition well suited for differentiation of soft tissue swelling (arthritis, tenosynovitis, bursitis) in the limbs (Kofler, 2009; Kofler & Martinek, 2004; Heppelmann et al., 2009). Furthermore, the same rectal probes are well suited for examination of a wide range of other organs, especially in calves but also in adult cattle, where the ultrasound wave penetration of these frequencies is enough to investigate some lung and pleural, abdominal, umbilical disorders or swellings elsewhere in the body (Flöck, 2007; Babkine & Blond, 2009; Franz et al., 2009; Steiner & Lejeune, 2009; Ollivett & Buczinski, 2016; Braun, 2016a,b) and for examination of the spinal cord (Testoni et al., 2012, 2014; Braun & Attiger, 2016).

Regardless of the applied diagnostic imaging techniques, an accurate anatomical differentiation of the (soft) tissue structures involved, characterization of the lesions, an early diagnosis, and a thorough preoperative inspection of incriminated region are of enormous benefit for determining an accurate prognosis as well as planning surgery and treatment and/or decision making (Braun, 2005; Braun et al., 2008b, 2011; Kofler et al., 2014; Ollivett & Buczinski, 2016; Braun, 2016a,b) in bovine patients.

RESET the mindset on antibiotic usage in dairy cows

T.J.G.M. Lam^{1,2,3}, R.J. Wessels^{1,4} and J. Jansen^{1,4}

¹ Communication in Practice, Nijmegen, The Netherlands

² GD Animal Health, Deventer, The Netherlands

³ Department of Farm Animal Health, Faculty of Veterinary Medicine, Utrecht University

⁴ St Anna Advies, Nijmegen, The Netherlands

Since the second world war, antibiotics came widely available to cure bacterial diseases, which had an enormous impact on lifetime expectation of diseased people. In the animal industry antibiotics were also used, initially to cure diseases, later also to prevent diseases and as growth promoters. The availability of antibiotics was of great importance for the improvement of animal health in the dairy industry, specifically related to udder health and to a less extent in claw health and uterine diseases. Due to the simple fact that antibiotics have an effect on the production process of products such as cheese and yoghurt, antibiotic use in lactating cows has always been limited.

In 2008 antibiotic usage in the livestock industry became a political issue in the Netherlands. Whereas antibiotic usage in humans was relatively low compared to other European countries, antibiotic usage in the Dutch livestock industry was relatively high. After a number of incidents with methicillin resistant *Staphylococcus aureus* (MRSA) and extended spectrum beta-lactamases (ESBL) in animals, reduction goals for antibiotic use in animals were set by our government. The goal set was a decrease with 20% in 2011, 50% in 2013, followed by 70% in 2015, as compared to 2009. At the same time it was indicated that the livestock industry itself had the responsibility to realize this reduction. In that same year a national taskforce was established in which the major livestock sectors participated.

At that time it was clear that, although the dairy sector was not the sector in which most antibiotics were used, there were some issues there too which had to be solved. The challenge in the dairy industry was to realize a reduction in antibiotic usage although usage was relatively low already. Over the years blanket dry cow therapy and extended treatment of (sub) clinical mastitis had been fiercely promoted, zero-withdrawal products were widely available and used. All of these were considered to have a positive effect on health and welfare, which we did not want to lose. What the specific issues were, what decisions were made and how we managed to reset the mindset of farmers and veterinarians, is described in this paper.

Antibiotic resistance in cattle

With respect to antibiotic resistance in dairy cattle, there is a huge difference between udder pathogens and other pathogens. It seems logic to focus on udder pathogens, because antibiotics are mainly used intramammary. Most bacteria, however, live in the intestinal tract, and that is where potentially most antibiotic resistance will develop.

In udder pathogens, antibiotic resistance is most prominent in Gram-positive bacteria, specifically staphylococci. Once in a while an ESBL will be found in milk, but that generally is considered as a contamination from the environment, rather than being an intramammary pathogen.

Resistance to methicillin in *Staph. aureus* is an issue related to penicillin resistance. Based on oxacillin testing and confirmed by the presence of the *mecA*-gene, MRSA has been monitored in the Netherlands since 2007. In 2008 a prevalence of MRSA of 2% was found in a prospective prevalence study in 200 dairy herds (Olde Riekerink et al., 2010). A total of 0.2% of the tested cows was positive on MRSA. All strains belonged to Spa-type t011 (ST398), indicating they were livestock-associated MRSA (Tavakol et al., 2012). These findings indicate that the prevalence of

MRSA in dairy milk is low as compared to for instance pigs (de Neeling et al., 2007).

With respect to Gram-negative bacteria, ESBL producing *E. coli* were found in a low number of milk samples (Hordijk et al., 2013). In faecal samples of young calves, however, ESBL prevalence is higher and comparable to other species. We currently are evaluating the dynamics of ESBL in calves and its relation with antibiotic usage in calves and in dry cow treatment.

Issues on antibiotic usage in the dairy industry

Most of the antibiotics used in dairy cows are used intramammary. In the Netherlands this used to be approximately 70% of total antibiotic usage of which roughly 1/3 in mastitis treatment and 2/3 in dry cow treatment (Kuiper et al., 2016). Because of withdrawal-time of antibiotics used to treat mastitis in lactating cows, this usage likely is as limited as possible. Of course udder health can be improved in many situations, but given the effort done in this field over the last years in our country, no major gains are expected here. For dry cow therapy that is different. From 2013 onward, blanket dry cow therapy (BDCT) was no longer allowed in our country, where it had been fiercely promoted in earlier years. It was expected that selective dry cow therapy (SDCT) would lead to an increase of clinical and subclinical mastitis (Scherpenzeel et al., 2014). In 2014 a guideline was launched by the Royal Dutch Veterinary Association, which stated that dry cow antibiotics were only allowed after intramammary infections (IMI) were diagnosed at drying off. As indication of IMI, somatic cell count (SCC) could be used. It was found that the cut-off levels of SCC did have a limited effect on the incidence of clinical and subclinical mastitis at the herd-level (Scherpenzeel et al., 2016). In spite of a reduction in the usage of dry cow antibiotics of approximately 28% in 2014, according to the Dutch Veterinary Medicine Authority, udder health did not decline enormously (Santman-Berends et al., 2016). In a thorough questionnaire it was found that in 2013, before they had much experience with it, most farmers were convinced that SDCT, and the selective use of antibiotics in general were a sound approach.

Apart from the quantitative approach, the types of antibiotics used also became important. Antibiotics used in the animal industry were subdivided in three categories, with increasing likeliness to give rise to development of antibiotic resistance. First preference antibiotics are considered to be effective for the specific indication and don't induce resistance by ESBL/AmpC production. Second preference antibiotics are only used when unavoidable. There has to be a specific documented reason like patient-history, sensitivity pattern or clinical urgency to use these antibiotics. Third preference antibiotics are those antibiotics that are of importance for treating multiresistant bacteria in human patients, such as 3rd and 4th generation cephalosporins, some fluoroquinolones and modern long acting macrolides. The use of third preference antibiotics is only allowed for individual animals, when bacteriological culture and sensitivity patterns showed there is no alternative.

The relation between antibiotic usage and antibiotic resistance in veterinary medicine has been shown in general (Chantziaras et al., 2014) as well as for specific antibiotics. In the United Kingdom it was found that herds that used 3rd or 4th generation cephalosporins were almost four times more likely to have ESBL producing *E. coli*, while no association was found with other antimicrobials (Snow et al., 2012).

Data on the usage of the different types of antibiotics are monitored on a national base by the Dutch Veterinary Medicine Authority (SDa), which is an independent institute that calculates antibiotic usage and sets benchmark indicators for the different animal species. The SDa consists of a panel of experts with a background in microbiology and epidemiology, both human and veterinarian. Since the launch of the differentiation system in 2012, the amount of third preference antibiotics used in the dairy industry decreased enormously, as is indicated for 3rd and 4th generation cephalosporins in Figure 1.

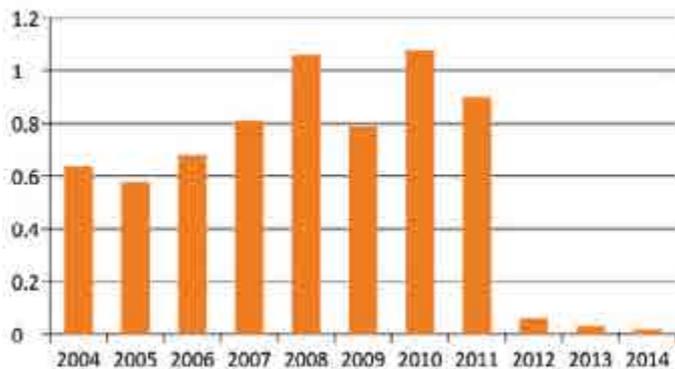

Figure 1. Use of third and fourth generation cephalosporins in the Netherlands in 2004-2014, expressed in animal defined daily dosages per year.

A final important aspect of antibiotic use in the dairy industry is residue handling. Consumption milk and milk that is processed are monitored very well, leading to a very low percentage of positive findings. In the past, however, very little attention was given to residues in waste-milk. This milk, that contained antibiotic residues in approximately 70% of samples (Heinrich et al., 2012) was often fed to young calves, in spite of the potential induction of antibiotic resistance (Brunton et al., 2012).

Changing the mindset

Traditionally veterinarians assume that dairy farming is an activity executed primarily based on rational, technical, and economic considerations (Burton, 2004). Although rational choices are crucial in farm management, we learned in mastitis studies that management is hardly ever fully rational (Jansen, 2010). One of the most used theories to understand people’s behaviour is the Theory of Planned Behaviour, described by Ajzen (1991) and by Fishbein and Yzer (2003). In short, this model says that if a farmer is actually willing to solve an issue, if he is positively influenced by important peers and if he has the feeling he can actually control and perform his actions, he will change his behaviour.

Based on the Theory of Planned Behaviour, the Health Belief Model (Janz and Becker, 1984), the Elaboration Likelihood Model of Persuasion (Petty and Wegener, 1999) and earlier work of van Woerkum et al. (1999) and Leeuwis (2004) we developed a model that is easy to use in practice, the RESET model (Figure 2).

This model fits very well as an explanation of the Dutch success in reduction of veterinary antimicrobial use, as described by Speksnijder et al. (2015). The different approaches used were found to be ingredients of the RESET model. It is important to use different approaches in a coordinated way to successfully influence the mindset. Because different people respond different to different stimuli, a ‘one size fits all’ approach assuming everybody will respond to it, will not work (Wessels et al., 2014). The behaviour of a group can therefore most effectively be changed using of a mix of different stimuli, which was done in the approach of decreasing antibiotic usage in the dairy industry in the Netherlands.

Figure 2. The RESET model (adapted from Van Woerkum et al. 1999, and Leeuwis, 2004).

The RESET model summarizes different models from literature in five important cues to action: regulation, education, social pressure, economic incentives and tools. Each may motivate a different group of people. With such a differentiated approach you hope to reach as much people as possible, trying to get over a tipping point.

The R of regulations, or rules force you to perform a desired behaviour. If rules are clear and if one is able to monitor whether rules are followed, they can be very effective. In the antibiotic discussion for instance, at some point it became clear that third preference antibiotics were no longer allowed. This was accepted and supervised by the SDa. The result is presented in Figure 1. Regulations, however, also are helpful for structure seekers, people who like to work according to a schedule that helps them to organize their work. The farm health and farm treatment plans as introduced in the Netherlands (Speksnijder et al., 2015) are examples of that.

A factor that traditionally is overestimated by veterinarians, but likely is underestimated in the antibiotics discussion, is education. Veterinarians generally are focused on teaching, delivering technical information, the rational approach (Burton, 2004; Jansen, 2010). The approach is that once a farmer will understand ‘how and why’, behaviour will change. This certainly is true for some farmers, but if it is the only approach, it will definitely not be sufficient. Interesting enough, in the antibiotics resistance discussion, the educative approach has hardly been used in the past. Many farmers did not know about the potential effects of the use of certain types of antibiotics on antibiotic resistance. All they talked about was efficacy, withdrawal time and prize. Veterinarians nor other advisors talked about the effect of suboptimal use of antibiotics on antibiotic resistance. Informing farmers on this issue certainly helped in reaching the numbers showed in Figure 1.

The probably most important factor in changing behaviour is social pressure. In most western countries society has changed in a few generations from a mainly agricultural society to one in which farmers are a minority. That has had its consequences on the way the general public thinks of farming and also on the way farmers think of farming. Those changes occur very slowly and differ from region to region, but they do occur. Once farmers stand up at meetings to tell about their experiences in hospital where they were isolated because they came from a farm, and explain they understand that, things are changing. Social pressure is also visible if farmers proudly tell in public meetings they have low antibiotic use in their herd, and are among the best in the benchmark. Exactly that is what happened in the Netherlands.

Although money certainly is not the only factor influencing behaviour, economics definitely is important. This is logic, because money is a major stimulus in the free-market economy. After the initial fear for the effect of taking away preventive antibiotics during the dry period, savings on expenditures on antibiotic use also influenced decision making by farmers.

Finally tools, technical facilities, also help in implementing behavioural change. The farm health and farm treatment plans are examples of this, as is the guideline on SDCT and the benchmark on antibiotic use at the herd level.

Conclusion

Antibiotic use and antibiotic resistance are important issues in the dairy industry, as they are in all parts of the livestock industry and in humans. For that reason, and because antibiotic use became a political issue, attention needed to be given to the subject. Since 2008 we earned experience on how to decrease antibiotic use in the Netherlands without leading to dramatic changes in udder health and in dairy health in general. We are convinced that cooperation of different stakeholders, being farmer organizations, dairy companies, veterinarians and others lead to a diversified approach that can be summarized in the RESET model. Because communication was taken seriously, taking into account that there is more than only rules, and combining multiple

strategies, the behavioural change regarding antibiotic use seems to be based on an actual change of mindset and therefore likely is successful on the long term.

Metabolic disturbances in neonatal calves with diarrhoea – clinical signs and treatment

Ingrid Lorenz¹, Florian Trefz²

¹Bavarian Animal Health Service, Poing, Germany

²Clinic for Ruminants with Ambulatory and Herd Health Services, Center for Veterinary Clinical Medicine, LMU Munich, Germany

Introduction

Neonatal calf diarrhoea remains one of the major health challenges in all bovine production systems. The infectious agents most commonly in diarrhoeic calves are *Cryptosporidium parvum* and rotavirus, followed by coronavirus and enterotoxigenic *Escherichia coli* (ETEC). ETEC usually only cause secretory diarrhoea in the first four days of life. The other common infectious agents involved in neonatal calf diarrhoea cause damage to the intestinal mucosa resulting in mixed malabsorptive and secretory diarrhoea. Irrespective of the causative agents the underlying pathophysiological mechanisms cause not only dehydration, but also several severe metabolic disorders. The purpose of this paper is to summarise the current knowledge on the clinical signs caused by the most important metabolic disturbances and their treatment.

Metabolic acidosis

Metabolic acidosis is a frequent complication of neonatal diarrhoea in calves and was traditionally attributed to intestinal losses of bicarbonate and an increase of blood L-lactate concentrations as a result of dehydration and concomitant tissue hypoperfusion.^{1,2} A well-known feature of metabolic acidosis in those animals is an increase of the anion gap, which indicates the presence of unmeasured anions when using the traditional Henderson-Hasselbalch approach. This increase could formerly not be explained by elevated L-lactate concentrations (Figure 1) and therefore resulted in an incomplete understanding of the pathophysiology of metabolic acidosis in neonatal diarrhoeic calves for a long time.³⁻⁵ However, this has been changed by the discovery that elevated blood D-lactate concentrations play an important role in the pathogenesis of metabolic acidosis in such animals⁶⁻⁸ (Figure 2).

The long-held view that faecal bicarbonate losses plays an important role in the development of acidaemia and metabolic acidosis in diarrhoeic calves has been questioned during the last decade.⁹ Application of the simplified strong ion approach to dehydrated diarrhoeic calves identified that acidaemia and strong ion acidosis was primarily due to a low strong ion difference as a result of hyponatraemia and an increase in unmeasured strong anions such as D-lactate. A non-volatile buffer ion acidosis, due to an increase in serum protein concentration was also identified to contribute to the acidaemia in dehydrated diarrhoeic calves.⁹

The simplified strong ion approach is based on Stewart's strong ion model^{10,11} and is conceptually differing from the traditional Henderson-Hasselbalch approach as it explains how 3 independent variables (partial pressure of carbon dioxide, the strong ion difference, and the concentration of nonvolatile weak acids such as albumin, globulin and phosphate) directly determine blood pH and bicarbonate concentration. A useful clinical application of the simplified strong ion acid-base model involves calculation of the strong ion gap instead of the anion gap in order to detect the presence of unmeasured strong anions in plasma.¹² Recently we found that a hyperphosphataemic acidosis is also frequently evident in dehydrated neonatal diarrhoeic calves and accounts in addition to D-lactate in large parts for the increase of the unmeasured plasma anion concentration, quantified by calculating the anion gap or strong ion gap. It is, however, likely that still unidentified anions like uremic anions are present in severely dehydrated calves which significantly contribute to the development of acidaemia.¹³

Irrespective of the cause of metabolic acidosis, intravenous treatment with sodium bicarbonate is the method of choice for diarrhoeic calves

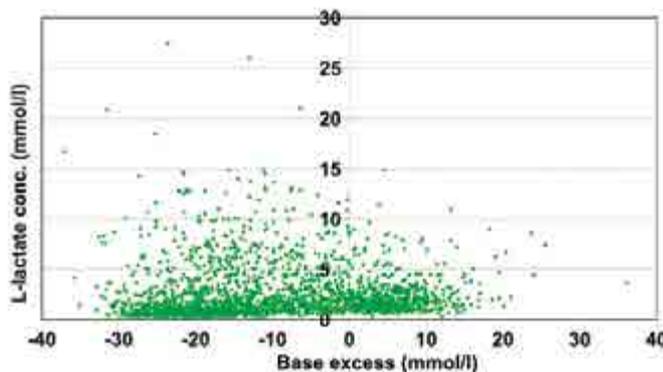

Figure 1: L-lactate concentration and base excess in 2019 calves with neonatal diarrhoea

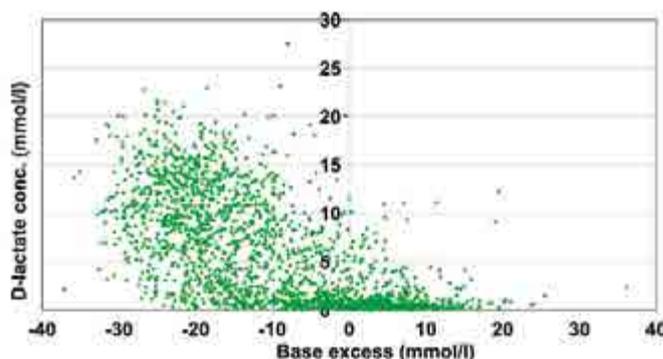

Figure 2: D-lactate concentration and base excess in 2019 calves with neonatal diarrhoea

that are considerably acidotic. The concentration and volume used can be varied according to the degree of dehydration. The amount of sodium bicarbonate needed for correction of acidosis can be estimated according to the clinical signs detected¹⁴ (Table 1).

Table 1: Estimation of the degree of acidosis in diarrhoeic calves with the help of clinical signs.

Clinical signs	Degree of acidosis	Therapy/required amount of sodium bicarbonate
Alert, standing, no dehydration	No acidosis	oral electrolyte solutions
Standing securely, enophthalmos	mild (BD about 10 mmol/l)	250 mmol (20 g)
Tired or listless, standing wobbly, has to be helped to stand up	moderate (BD about 20 mmol/l)	500 mmol (40 g)
Apathetic to comatose, sternal or lateral recumbency or barely able to stand and impaired palpebral reflex	severe (BD over 20 mmol/l)	750 mmol (60 g)

D-Lactataemia

Until the 1980s, D-lactic metabolic acidosis was only known to occur in adult ruminants due to acute ruminal acidosis after carbohydrate overload.¹⁵ In calves the production and accumulation of D-lactate was

first described in the context of ruminal drinking. After it has been known for a while that the accumulation of milk or other solutions containing readily fermentable carbohydrates predominantly leads to lactic fermentation in calves, it could be shown that continuous force-feeding of milk not only led to accumulation of D-lactic acid in the rumen, but also to D-lactataemia.^{16A} It was only after the development of stereospecific assays^{17,18} for the measurement of D-lactate hugely facilitated research in the area, that its importance in the context of neonatal calf diarrhoea was discovered.

Carbohydrates that escape digestion and absorption in the small intestine due to enteritis represent a rich fermentative substrate for colonic bacteria growing in the large intestine. The subsequent acidification of the intestinal milieu favours lactic acid producers, resulting in generation of larger amounts of L- and D-lactic acids. Multiple studies indicate the intestines as source of D-lactate in diarrhoeic calves. Researchers found elevated D-lactate concentration in the faeces of diarrhoeic calves when compared to healthy controls, and/or could demonstrate D-lactic metabolic acidosis in diarrhoeic without elevation of D-lactate concentrations in the rumen.^{6,8,19-21}

In calves with neonatal diarrhoea the risk to develop D-lactic metabolic acidosis is age dependent.²² In general calves that suffer from diarrhoea within their first 5 days of life have significantly higher base excess and significantly lower D-lactate concentrations than older calves (Figure 3). Koch and Kaske²³ described that calves infected with enterotoxigenic *Escherichia coli* were younger and less acidaemic than calves suffering from neonatal diarrhoea caused by viral or cryptosporidium infections. This is compatible with the hypothesis that an increase in production of D-lactate in diarrhoeic calves results from villous atrophy in the small intestine with maldigestion and malabsorption and subsequent microbial fermentation of substrates in the large intestine.⁶ In a study investigating D-lactate concentrations throughout the gastrointestinal tract of calves that have been euthanized for various medical reasons, elevated D-lactate concentrations were found throughout the entire gastrointestinal tract in some calves. In these calves significantly more Gram-positive rods could be found in the abomasum, the distal part of the jejunum, the caecum and the colon when D-lactate was present (>3 mmol/L), compared to cases with negligible concentrations of D-lactate at the respective locations. At present, it can only be speculated as to

whether D-lactate is actually produced throughout the whole intestinal tract, or only in circumscribed areas and subsequently distributed by means of intestinal motility.²⁴

The serum D-lactate concentration plays a major role in the development of the clinical picture in calves with diarrhoea. It has been shown in diarrhoeic calves that D-lactate concentration was associated with impaired posture, behaviour, and especially impairment of the palpebral reflex, whereas the sucking reflex appeared to be influenced by dehydration and metabolic acidosis.²⁵ Experimentally induced severe D-lactataemia without acidosis also resulted in profound changes in posture, behaviour, and palpebral reflex in healthy calves.²⁶ Induction of hyperchloraemic metabolic acidosis with a mean base deficit of up to 22.4 mmol/L with an IV infusion of 4000 mL of a solution containing 400 mmol HCL in 0.9% NaCl over a period of 80 min in healthy calves did not cause any central nervous system (CNS) signs.²⁷ In prolonged hydrochloric acid (HCl)-induced metabolic acidosis, however, a mild depression of neurological function could be observed. In this study acidosis was produced by infusion of either isomolar DL-lactic acid, L-lactic acid, or HCl, respectively, over a period of 6 h. Only DL-lactic acidosis was associated with severe disturbances in neurological functions (i.e. ataxia, and depressed menace, palpebral and tactile reflexes), whereas either form of acidosis triggered depression of the sucking reflex.²⁸

Even though the serum D-lactate concentration is helpful for the clinical assessment of the degree of metabolic acidosis there is no need to take it into special consideration for therapeutic measures, since D-lactate concentrations decrease regularly within 24 to 48 hours of initiation of therapy targeted at correction of dehydration and acidosis.²⁹ The mechanism that leads to normalisation of D-lactate values is not completely clear. Most likely it is caused by a combination of increased renal excretion triggered by enhancement of renal perfusion due to rehydration, and decreased production due to the correction of metabolic acidosis. It can be speculated that this happens due to alkalinisation of the intestinal lumen after the deficit of bicarbonate is corrected.³⁰

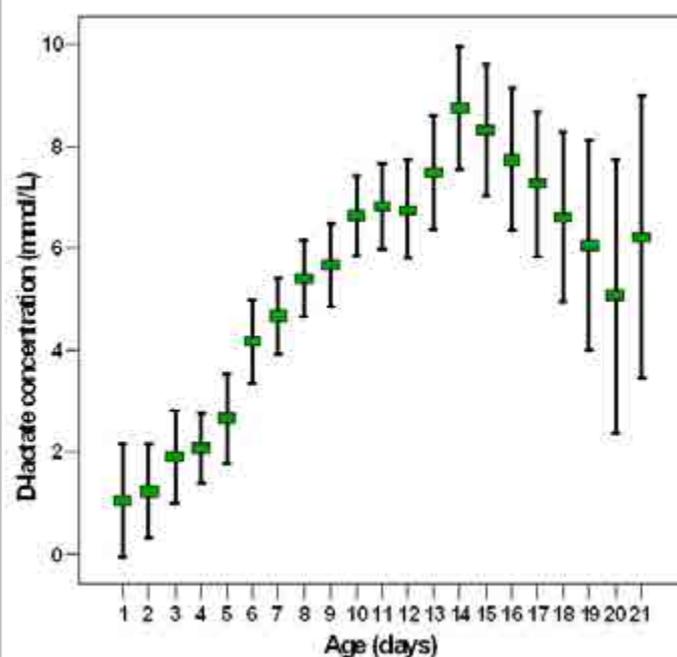

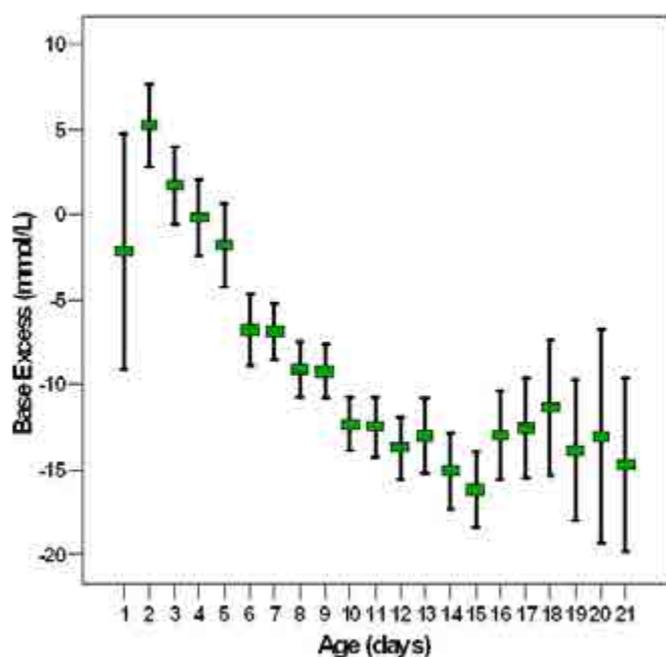

Figure 3: Base excess and serum D-lactate concentration (mean \pm 2SE) related to age in 2019 calves with diarrhoea upon admission.

Potassium balance disorders

Electrolyte imbalances are common in neonatal diarrhoeic calves and are closely linked to derangements of acid-base status. Although neonatal diarrhoeic calves have a clear negative potassium balance due to intestinal losses and low milk intake,³¹ data of a large study population of hospitalised calves indicate that they usually show normo- or even hyperkalaemic plasma concentrations.^{32F}

Hyperkalaemia is a clinically relevant electrolyte imbalance in those animals and has historically been attributed to an acidaemic state with intracellular buffering of hydrogen ions and impairment of the Na⁺/K⁺-ATPase on cell membranes with subsequent diminished intracellular translocation of potassium ions as the proposed underlying mechanisms.^{33,34} In classic publications, the response of plasma potassium concentration has been characterized by a linear increase of 0.3 to 0.6 mmol/L for every 0.1 unit reduction in blood pH.^{35,36} However recent studies indicate that the presence of a hyperkalaemic state in diarrhoeic calves strictly depends on the nature of an existing acidosis but not on acidaemia per se. Especially D-lactic acidosis is only rarely associated with increased plasma potassium concentrations and was identified as a protective factor for the development of hyperkalaemia. More importantly plasma potassium concentrations in diarrhoeic calves are most closely correlated to clinical and laboratory indices of dehydration, which indicates that a decrease of renal glomerular filtration rate plays a central role in the development of a hyperkalaemic state.^{32,37,37}

Clinical alterations of hyperkalaemia are related to an impaired neuromuscular excitability which is further exacerbated by the presence of hyponatraemia and metabolic acidosis,³⁸ conditions which are usually present in affected calves. Due to the potential cardiotoxicity (Figure 4), acute hyperkalaemia represents a potential life-threatening state and was traditionally considered to be an important cause of death in diarrhoeic calves.¹ Electrocardiographic manifestations typically include large and spiked T-waves, increased QRS-duration, flattened or missing P-waves and potentially R-R irregularities.^{33,39-41} However an ECG is rarely available in ambulatory practice, and there are also typical clinical signs that should alert the examiner to the presence of hyperkalaemia. In our experience, bradycardia or cardiac arrhythmias are rarely detectable and the latter had also a low sensitivity for the detection of a hyperkalaemic state in an observational study.³⁷ More reliable findings include severe clinical dehydration, cyanosis and especially impairments of ability stand.³⁷ The latter is likely related to skeletal muscle weakness which is also a prominent feature in hyperkalaemic human patients.⁴² Hyperkalaemia in diarrhoeic calves can therefore produce a clinical picture which is somehow comparable to marked D-lactic acidosis. However since a hyperkalaemic state in diarrhoeic calves is usually accompanied by normal or only slightly elevated plasma D-lactate concentrations, those animals usually exhibit a normal palpebral reflex, which allows to clinically distinguish between those two conditions.

Acute hyperkalaemia should be considered as an emergency and many affected calves are presented with signs of shock or in a somehow "labile" state. Stress needs to be avoided as much as possible and treatment objectives should focus on a rapid stabilization of the calf. In this respect, hypertonic infusion solutions such as 8.4% hypertonic

sodium bicarbonate or 7.2% NaCl have a sound physiological basis in the initial treatment of affected calves.⁴³ Those infusion solution induce a rapid plasma volume expansion, potentially enhance the redistribution of potassium ion into the cells, and have the ability for a rapid reversal of electrocardiographic manifestation.⁴³ However hypertonic saline might be inferior to sodium bicarbonate as it does not correct concurrent acidaemia which is usually present in those calves. A recent study showed, that intravenous administration of hypertonic sodium bicarbonate in a dosage of 250-500 ml indeed induces an immediate and sustained potassium lowering effect which was most closely correlated to an increase in venous blood pH.⁴⁴ In that study, a subsequent decrease of plasma potassium concentrations was further associated with changes of hydration status, such that we currently recommend to additionally infuse larger volumes of crystalloid infusion solutions. Glucose containing infusion solutions might have an additional beneficial effect in this respect due to an insulin-dependent transcellular shift of potassium ions.

As outlined above, hypokalaemia is a rare finding in neonatal diarrhoeic calves, especially if they are suffering from metabolic acidosis and/or dehydration. However, in a recent study the proportion of hypokalaemic calves after 24 hours of fluid therapy was reported to be twice as high as on admission to a veterinary teaching hospital. A hypokalaemic state was especially prevalent after 24 hours of therapy in calves which suffered from severe metabolic acidosis, had a low intake of milk and a long history of diarrhoea,⁴⁵ which is likely related to a depletion of body potassium stores. Hypokalaemia was not found to be associated with any clinical alterations in that study. However further studies are necessary if such diarrhoeic calves benefit from oral or parenteral administration of potassium salts.

Figure 4: Electrocardiographic findings in a hyperkalaemic neonatal diarrhoeic calf including arrhythmias and missing P-waves (plasma potassium concentration 9.4 mmol/L).

Managing Liveweight Production From Beef Breeding Herds

Introduction – asking the right question

Too often when the question is asked, 'How is your beef breeding herd going?' the answer is a performance measure such as the proportion of cows pregnant or calves weaned. However, profit is primarily a function of live weight production, its value, and the cost of production. Therefore, the question should be 'How many kilograms of live weight do you produce annually from this management group (herd) of breeding females per hectare?' For example, if the farmer puts 100 tonne of cows in a paddock after completing pregnancy diagnosis of the herd then 12 months later how many tonnes of beef have been harvested from the herd (includes calves weaned and any cows and bulls sold). The role of veterinarians consulting to beef breeding farms should be to develop management strategies to improve herd live-weight production and identify opportunities to reduce cost of production. However, beef cattle farmers typically use veterinarians only to conduct pregnancy diagnosis, breeding soundness examination of bulls, and investigate outbreaks of disease or lower than expected reproductive performance.

Measuring live weight production and fertility of beef herds

Annual pregnancy diagnosis and foetal aging, assessment of lactation status at branding and weaning, and weighing a representative sample of cows and weaned calves provide the data required to define liveweight production and fertility of breeding herds. Transrectal foetal ageing enables estimation of month of conception and calving, which when conducted in two consecutive years enables the interval from calving to conception to be estimated. Assessment of lactation status after the expected period of calving enables determination of the incidence of foetal and calf loss. Summarising the data in the form of predicted month of calving histograms informs decisions on when to conduct branding or weaning, and enables the veterinarian to identify potential causes of reduced performance (Figure 1).

Relatively simple paper-based recording systems have been developed by Fordyce et al. (2014a) that enable live weight production and performance of beef breeding herds to be monitored. However, adoption of these recording systems has been highly variable with many extensive rangeland farmers in particular, still unable to accurately count the number of females on their farm or the number of calves weaned annually. The development of electronic identification (EID) systems to enable crush/chute-side and remote electronic data capture can be effective in monitoring the production and performance of extensively managed beef cattle (McGowan et al. 2014a; Swain and Friend 2013).

Operating herd management software using a ruggedized laptop and an electronic enter pad connected to an EID reader mounted to the crush/chute and electronic scales mounted under the crush/chute enables capture of 12 to 20 pieces of data on cattle at typical processing rates of 60 to 100 animals per hour (McGowan et al. 2014). Currently, the major limitations of this system are loss of EID tags from cattle, estimated at about 8% within 3 years of insertion in a tropical rangeland environment (McGowan et al. 2014a), and the inability to complete data analysis on the day of data capture. Cloud-based systems will allow real-time assessment of individual management information through viewing and recording farm data from any location using many devices (eg, laptops, phones, tablets). This will also enable interconnectivity for external on-the-fly data analyses that could validate data plausibility and estimate individual and management group production and performance indices.

Predicting live weight production that can be sustainably achieved by breeding cattle

Beef breeding herd management varies considerably across the world, but the fundamental principles remain constant. A key principle is to know what level of live weight production a specific feed resource, usually native or improved pasture, is capable of sustaining. In a large study of factors affecting the reproductive performance of commercial beef breeding herds in northern Australia (McGowan et al. 2014a) farmers/managers were asked estimate average annual growth of yearling steers if they grazed the pastures grazed by the heifers and cows enrolled in the study. Mean annual steer growth varied from 100 to 200kg associated with large differences in soil fertility and vegetation type. One easily measured estimate of live-weight production from breeding herds/management groups is weaner production (kg/cow = total weight of calves weaned / the number of cows retained for calving and then mating in the next year). McGowan et al. (2014a) demonstrated that commercial weaner production was on average equivalent to annual estimated steer growth. Research is currently being conducted in northern Australia to further investigate whether routine grazing of

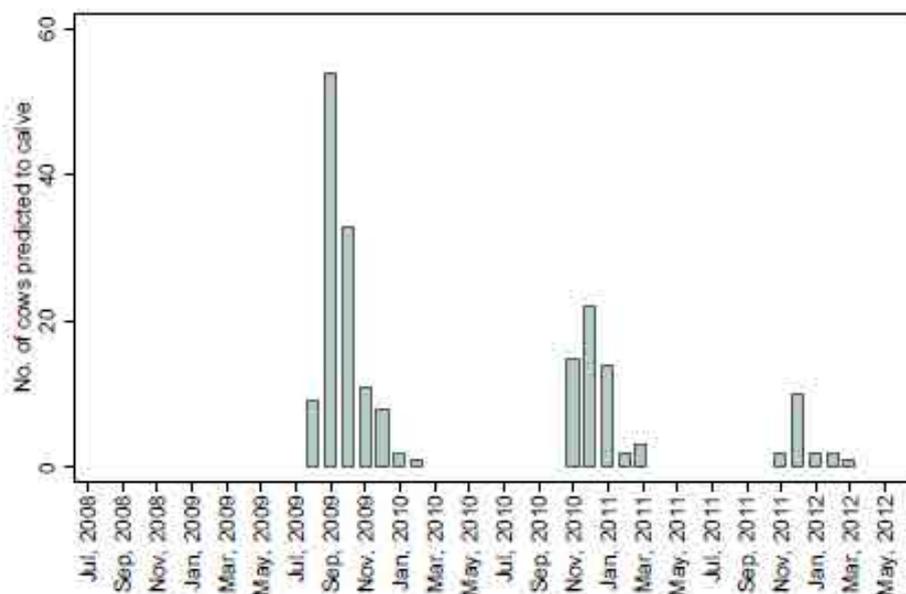

Figure 1. Calving pattern for a group of heifers that were monitored for 3 years in a herd which had a defined mating period. Note the shift to the right in month of calving which reduces the opportunity for late calving females to reconceive.

a sample of representative yearling steers in each paddock grazed by cows and heifers can be used to estimate the expected average weaner production from these paddocks. Clearly, because of the often marked variation in seasonal weather conditions this approach will need to be conducted over at least three years to obtain a reasonable estimate of average weaner production.

Beef farmers often aim to achieve a certain average weaning weight which may not take into account the feed resource(s) they have available for their cattle. For example, if the annual estimated growth of steers in a particular situation is 100kg and the average weight of calves weaned is 200kg, where does the additional 100kg come from? Clearly, it has to come from mobilisation of fat and protein reserves from the heifer or cows that produced these calves. In this low annual growth environment, these cows may lose 100kg during lactation (2 body condition scores - 1-5 scale), and as a consequence are unlikely to reconceive and have an increased risk of mortality. The farmer may then be forced into supplementary feeding to prevent cow mortalities; but then the question must be, 'is this intervention likely to be profitable'?

Farmers often want to know what level of production they should be aiming for. Although benchmarking herd or management group production causes angst amongst some economists, this is entirely valid if referenced against a measure of what the specific feed resource is capable of producing. An example of this approach is provided in Table 1.

Table 1: Annual weaner production from management groups of cows in northern Australia against estimated annual average steer growth (McGowan et al. 2014a)

Mean annual steer growth (kg)*	No. of herds	Weaner production (kg/cow)		
		25 th percentile	Median	75 th percentile
200	33	164.0	191.0	240.0
180	33	160.7	194.6	220.1
170	29	134.9	163.0	182.6
100	59	74.0	93.3	112.4

*Estimated growth of steers grazing same pasture as cows

What are the major drivers of live weight production of a breeding herd

The concept of live weight production (McGowan et al. 2014a) is that over a one-year production cycle, a cow's production, if she remains alive, is the sum of her live weight change, and the weight of any weaned calf. The business makes money by selling the annual live weight produced either directly, or after transfer to another sector of the herd for value adding. This is equivalent to how any business measures productivity.

McGowan et al. (2014a) demonstrated that no single performance measure of a population of commercial beef breeding herds in northern Australia was predictive of annual live weight production. However, this is not surprising since no measure of fertility takes into account heifer/cow mortality or annual change in live weight. Using annual live weight production as a primary measure of "how a herd is going" encourages a more holistic approach to herd management. However, regardless of whether beef breeding herds are control mated or mated continuously, key drivers of live weight production are the percentage of lactating cows pregnant within 4 months of calving (estimates the proportion of cows likely to wean a calf in consecutive years), the annual total percentage of pregnant cows, the percentage of foetal and calf loss between confirmed pregnancy and weaning, average weight of weaned calves, live weight change of heifers/cows and percentage heifer/cow mortality.

Developing management strategies to increase live weight production and reduce cost of production

It does not matter whether you are consulting to breeding herds of 5 cows or 150,000 cows, the critical influence of nutrition on reproductive performance is the same. Too often undue emphasis is placed on investigating infectious diseases and trace element deficiencies rather than focussing on body condition of heifers and cows in the last trimester of pregnancy and first 3 months of lactation. The major factors affecting the percentage of cows becoming pregnant within 4 months of calving and percentage of pregnant females failing to wean a calf in tropical rangelands typical of northern Australia have been described by McGowan et al. (2014b) and Fordyce et al. (2014b), and in many cases are remarkably similar to those identified as being important in more intensive temperate beef breeding regions of the world. The overall approach we recommend is after defining the likely factors affecting production and performance implement 'best practice' management strategies which are summarised as:

Manage the feed-base

You cannot make something from nothing. Cattle can only achieve net live weight production if energy and protein intake is above that required for maintenance. Beef breeding businesses are built on ready access to productive, palatable, nutritious pastures and good quality water. The principles of 'best practice' grazing management must be understood and implemented.

Key management practices

- Budgeting available feed to meet short and medium term cattle requirements
- Good grazing management to allow pasture recovery, eg, rotational grazing, or in tropical rangelands deliberate withholding of grazing of selected paddocks over the wet season
- Limit grazing distance from water to <2.5 km where possible
- Active pasture development and rehabilitation
- Fencing to control overutilization of preferred land types including riparian zones
- Use supplements that augment sound basic management. For example feeding supplemental phosphorous to late-pregnant heifers and first-lactation cows where risk of phosphorous deficiency is high. If good grazing management and lactation management practices are implemented then feeding of nitrogen supplements during the dry season in arid tropical rangelands may only be necessary during periods of severe drought.

Manage lactation

Cows have amazing capacity to meet their energy, protein and macro-mineral requirements from available pasture and mobilisation of their own body tissue reserves. However, where cattle draw down on their body tissue reserves (eg, during lactation) this must be followed by a period of re-alimentation in preparation for the next reproductive cycle. Thus the timing of weaning is critical because cows must have sufficient access to pasture of adequate quality to replenish body tissue reserves prior to the next calving event.

Key practices

Manage weaning to conserve body condition of cows in preference to achieving high live weight weaners, ie, the decision on timing of weaning should be made on the basis of cow body condition, not an average weaning weight target.

Use pregnancy diagnosis and foetal aging to segregate cattle for different nutritional management and efficient weaning. It is particularly important that heifers are managed as a discrete group until they are confirmed

pregnant after calving for the first time. Also in continuously-mated herds identification of heifers and cows likely to calve at a time when pasture quality and quantity is very limited is critical to minimising cow and calf mortalities.

Wherever possible mating should be controlled to ensure heifers and cows calve close to the time when the likelihood of significant improvement in seasonal pasture quantity and quality is high. Alternatively in continuously-mated herds use foetal aging to segregate cows into approximately 3-month calving periods which can be matched with feed available, handling and husbandry.

Manage cattle health & stress

This primarily involves implementation of evidence-based control strategies to prevent infectious causes of heifer/cow death (eg, clostridial diseases including botulism, babesiosis), clinical illness (eg, bovine ephemeral fever), subclinical disease (eg, external/internal parasites), and infectious causes of embryonic, foetal and calf loss (campylobacteriosis, trichomoniasis, bovine viral diarrhoea virus). Also breeding females and their offspring may be exposed to a wide range of environmental stressors which can severely impact on both survival risk of the calf and the dam.

Key practices

A risk-based approach to control of infectious diseases should be used involving assessment of the immune status of the dams including determination of whether the herd or management group is endemically infected, and risk of introduction of infection.

Provide protection from environmental extremes (floods, blizzards, heat wave), especially for young calves and their dams

Where possible, avoid handling calves less than one month of age

Manage breeding

Bull fertility and genetics have a profound effect on business outcomes and herd productivity. Frequently the 'low hanging fruit' in a beef breeding business is the bull percentage used. In a study of bull selection and management McGowan et al. (2014a) found that approximately three quarters of farmers or managers used above the recommended 2-2.5% bulls. Bull costs per calf born are an important cost eg, if the average cost of replacement bulls is \$4,000 and bulls are mated at 2% versus 4% then the annual costs per calf assuming a weaning rate of 80% are \$14 and \$27, respectively.

Key practices

- Establish a genetic improvement program to achieve long-term increases in fertility as well as improvements in traits such as carcass quality, and in harsh environments, adaptive traits
- Select replacement bulls that have passed a breeding soundness evaluation. Select physically-sound bulls with at least average scrotal circumference for breed and live weight, and greater than 70% normal sperm.
- Replacement bulls should be introduced to the farm at least 4 months prior to use. They should be vaccinated against known causes of death, illness and reproductive loss.
- Mate at no more than 2.5% sound bulls.
- Select bulls from dams that have weaned a calf from their first two mating opportunities.
- Bulls should be managed to ensure they maintain satisfactory body condition (at least BCS 2.5 - 1-5 scale). Treatments to control external and internal parasites are recommended as bulls generally carry higher burdens of both.
- Herd bulls should undergo at least a general physical examination and detailed examination of the external genitalia annually prior to

mating and bulls should be considered for culling when they reach 8-9 years of age.

Initiating adoption of management changes – how successful have we been?

In preparing this paper we are very conscious that David Mossman, Basil Lowman and Keith Entwistle beautifully described the approach to improving reproductive performance in a series of publications in the '70's and '80's. However, adoption by farmers and managers of many of their recommendations has been disappointingly slow; eg, McGowan et al. (2014a) reported that in northern Australia only about a quarter of farmers/managers routinely used a breeding soundness examination including microscopic examination of semen to select replacement bulls. As veterinary advisors to beef breeding herds we have to accept that in many cases we have failed to effectively communicate how and why producers should adopt recognised 'best practice' recommendations. In some cases we focus only on the potential positive benefits of our recommended changes to management without equally acknowledging the potential negative outcomes. A good example of this is where a farmer adopts your recommendation on lactation management which results in a significant increase in the proportion of the herd becoming pregnant within 4 months of calving and thus contributing a weaned calf each year. If the farmer does not adjust his/her culling and selling strategies then there is a significant risk of overgrazing and degradation of the pasture. Further, too often we assume that the terms we use are universally understood by farmers yet there is clear evidence that in many cases there is considerable confusion amongst farmers, advisors and veterinarians; eg, the definition of weaning rate is highly variable.

Take home messages

- Understand what live weight production your client's beef breeding herd's feed resource is capable of sustainably supporting.
- Measure the actual production and performance of each breeding management group or herd you consult to.
- Understand the key drivers of live weight production from beef breeding herds.
- Understand how to cost effectively control the major factors affecting these drivers of live weight production

Bovine abortion/stillbirth investigation: a practitioner-focused approach

John F. Mee

Animal and Bioscience Department, Teagasc, Moorepark Research Centre, Fermoy, Co. Cork, Ireland; john.mee@teagasc.ie

Introduction

Abortion and stillbirth diagnosis rates do not appear to have improved over time internationally despite the development of molecular diagnostic techniques and the discovery of new abortifacients. While reasons for the overall low diagnostic rates from fetal investigations are detailed hereunder, this paper addresses this challenging conundrum with a view to practitioner-led improvements in diagnostic rates.

'Observed abortion'

From a practitioner and their clients' perspectives, abortion may be defined as the expulsion of a non-independently-viable fetus before full-term that is likely to be observed (and possibly submitted for examination) by a farmer, i.e. an 'observed abortion'. Irish data suggest the period of risk for an observed abortion is from 120 to 260 days of gestation (Mee and Sanchez-Miguel, 2015). The fetus at 120 days is the size of a small cat with a crown rump length (CRL) of 20-30cm and weighs ~1kg.

an abortion can be defined for practical purposes as the expulsion of a visible, but non-viable, fetus

The majority of laboratory-investigated abortion cases are from the last trimester (Table 1), while the majority of non-submitted abortions are from the first two trimesters; this leads to under-estimation of real abortion rates (Thurmond et al., 1994). For example, over 95% of aborted foetuses submitted to an Irish regional veterinary laboratory were from the fourth month of pregnancy on (>120 days), (Table 1).

Table 1. Gestational age of laboratory-investigated aborted foetuses over a 25-year period.

Trimester	Month of gestation	Fetuses (No.)	%
First (early)	2	73	0.7
	3	298	2.9
Second (mid)	4	841	8.2
	5	1393	13.7
	6	2069	20.3
Third (late)	7	2858	28.0
	8	2661	26.1

Source: Cork RVL, 10,193 fetuses (1980-2003)

'Stillbirth'

Perinatal mortality may be defined as death of the fetus or perinate before, during or within 48 hours of calving at full term (≥ 260 days) (Mee et al., 2014). While 'stillbirth' is commonly used as a synonym for perinatal mortality it may be defined as the birth of a fetus before or during calving at full term. These gestational and perinate age thresholds are arbitrary and vary both intra- and inter-nationally.

REPORTING OF FETAL/PERINATAL MORTALITY

Before addressing the titular topic; investigation, the issue of reporting needs to be addressed as it is equally if not more important.

Under-reporting

Under-reporting is a major issue with bovine fetal/perinatal mortality internationally. To some risk-averse clients the loss of a single valuable pregnancy may trigger a veterinary investigation (threshold for investigation) while for the majority of clients multiple losses need to occur before this threshold is exceeded. A few abortions in large herds are 'expected', i.e. abortion is considered a 'normal' event as long as it is sporadic. In a French study only 20% of beef farmers who had an abortion or stillbirth reported it (Bronner et al., 2013). A fetal mortality rate of $\geq 5\%$ is the investigation threshold used by the majority of veterinary respondents in the EU (Bronner et al., 2014). However, a cluster of cases is a more important 'tipping point' for investigation in seasonal calving herds, than % of pregnancies aborted.

a cluster of abortions is a more important tipping point for investigation than % of pregnancies

Proximity to the laboratory, number of losses, 'farm blindness' and lack of understanding influence the likelihood of sample submission.

UNDER- AND OVER-TRIAGE

The approach to a sporadic abortion/stillbirth in a herd without a history of problems will differ from that in a herd with a series of cases. This is referred to as under-triage, whereby such sporadic cases are not investigated as thoroughly as cases from multiple mortality herds. However, over-triage may be warranted even for sporadic cases on farms a long distance from the local laboratory as resubmission of material is less likely. One cannot predict that the index abortion case is not the first of many in a herd outbreak.

all abortion 'storms' start with a single case

Studies have shown that of abortions only approximately 20 to 30% are observed (Gadicke and Monti, 2013) suggesting that in many cases the first case presented (index case) is not in fact the first case that occurred, merely the first that was observed.

PROBLEM HERDS

The herd-level occurrence of abortions/stillbirths follows a right-skewed distribution with most herds having no or low losses but a minority of herds have high losses. The threshold at which loss prevalence becomes a 'problem/cluster/storm', and hence is investigated, is usually defined by the herdowner. Norm-referenced thresholds are cohort-based which may reflect the national recorded abortion rate. Criteria-referenced thresholds are based on metrics other than those based on cohorts, e.g. a theoretical or empirical threshold. While the latter has traditionally been 2% for abortions, it is suggested a higher figure may be more appropriate to include non-observed abortions (Mee and Sanchez-Miguel, 2015).

VETERINARY PRACTITIONER-LED ABORTION/STILLBIRTH INVESTIGATION

When approached by a client with an aborted cow or a stillbirth problem (as defined above) the following standard operating procedure (SOP) is recommended.

SOP FOR ABORTION/STILLBIRTH INVESTIGATION

This involves three simple steps; collect a history, examine pregnant animals and examine the foetus/placenta.

1. Collect a history

First establish the nature and extent of the problem by investigating possible risk factors associated with the loss/es. Standard questions to ask include how many cows have aborted/had stillbirths, how many cows are pregnant, what fetoplacental material is available, is the dam sick, are most losses in heifers, and recent husbandry changes. A proforma questionnaire is used by veterinary laboratory staff to collect the history

prior to the postmortem examination; practitioners might consider using such a format for problem herds. In addition to collecting information on the individual abortion/stillbirth, the herd health history is important. For example, last vaccinations against fetopathogens, recent cattle purchases and bulk milk test (BMT) test results.

2. Examine/sample the pregnant and aborted/stillbirth animals

The pregnant cohort

Examining the pregnant animals and their environment allows the practitioner to assess their general health, body condition score (BCS) and feeding management. Cohort sampling of dams in the affected group can be useful in determining micro/macronutrient status and differences in exposure (presence/absence, prevalence) between affected and unaffected dams (case-control); but vaccinal status needs to be known.

The dam

Clinical examination of the dam may reveal pyrexia, diarrhoea, respiratory signs, etc. A faecal sample may be useful where salmonellosis is suspected. Single blood samples from aborted cows are the most common samples collected to investigate bovine abortion (sero-diagnosis). These are moderately useful as proxy samples for fetal material. For example, a single blood sample from the dam of an aborted fetus can be up to 85% accurate (non-vaccinated cows) in predicting a fetal culture-positive result (e.g. Salmonella Dublin), (Sánchez-Miguel et al., 2011). However, the primary value of maternal serum is as an exclusionary test for maternal antibody, i.e. a negative result rules out some causes, e.g. Neospora caninum. a single dam blood sample is 85% accurate in diagnosing S. Dublin abortion

Paired sera (more than two weeks apart) may detect rising titres (two to four-fold) for some abortifacients (e.g. S. Dublin SAT) but not for others (e.g. Leptospira spp. Neospora) due to the lag phase between infection and fetal mortality. In vaccinated herds natural infection can still be distinguished where DIVA vaccines are used (gE-deleted BHV) and where titres are much higher than those expected from vaccination (e.g. Leptospira) this suggests current, active infection.

**3. Examine the foetus and placenta
ABORTION/STILLBIRTH FETOPSY SOP**

As with a clinical examination on a live animal a systematic approach means that important lesions are not missed due to focusing on the obvious lesion/s; this involves three steps - external and internal examination and sampling the carcass.

1. External examination

The external examination will confirm the animal identification, fetal preservation, maturity, size for date/plurality, and detect defects, discharges and predation. The stage of development of the foetus may be estimated from its body weight, size (e.g. crown-rump length; CRL), (Table 2) and external developmental indicators (dentition, pilosity).

Table 2. Physical characteristics of aborted foetuses at different months of pregnancy

Month of gestation	Body weight (kg)	sCRL* (cm)
6	5	50
7	15	70
8	30	90
9	40	95

*sCRL = straight crown-rump length.

Gestational age may be estimated from sCRL as follows: gestational age (days) = 68 + 2.25 x CRL (cm)

2. Internal examination

An illustrated guide to bovine fetopsy by the practitioner has recently been published (Mee, 2016).

3. Sampling the carcass

A sample selection algorithm for aborted/stillborn fetuses is outlined in Figure 1. It is not possible to be prescriptive about test selection as laboratories differ in the test menu and tiers they offer. Test selection will also be determined by the anamnesis, degree of carcass autolysis and costs. Rather than 'necropsy by algorithm' the decision-making of the pathologist still determines whether to collect samples. Additionally, samples can be discarded if collected in the early stages of the necropsy where subsequent examination reveals the likely cause does not require laboratory testing.

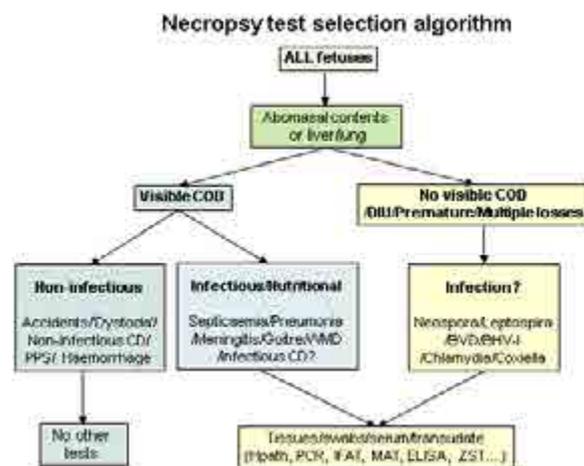

Figure 1: Practitioner-focused necropsy sample selection decision tree for aborted/stillborn foetuses (COD=cause-of-death, CD=congenital defect, DIU=dead in utero)

Microbiology samples

Abomasal contents can be sampled aseptically by searing the abomasal serosa with a heated scalpel blade and aspirating a sample into a plain vacutainer tube. In general, tissue samples are preferable to swabbed samples and surface swabbed samples are preferable to fluid swab samples. If an abomasal sample is unobtainable (due to scavenging) or if septicaemia is suspected, lung, liver or brain samples are suitable alternatives. Brain sampling is of particular value in scavenged and mummified foetuses.

Serology samples

Serological sampling can be useful after the first trimester (>120 days) when the foetus is immunocompetent as antibodies indicate fetal infection (but not necessarily fetopathy, e.g. Neospora congenital infection), assuming placental competence.

Trace element samples

Examination of the thyroid for goitre and submission of a fresh (I₂ content) and formalinised lobe (histopathology) will detect possible iodine deficiency. Where selenium deficiency is suspected a sample of the liver or kidneys should be submitted.

Histopathology samples

Samples for histopathology should include normal and abnormal tissue and should not be greater than 1 cm thick and 2 cm long. Many pathologists routinely sample lung, liver, thyroid, heart and brain. As the brain is of particular value in the histopathological diagnosis of neosporosis, submission of the skull or entire brain is recommended.

Table 3. Standard and additional samples to collect from aborted and stillborn fetuses*

For investigation of	Standard samples	Ancillary samples	Comments
Fetopathogenic bacteria and fungi (e.g. <i>Aspergillus</i> spp., <i>B. licheniformis</i> , <i>L. monocytogenes</i> , <i>T. pyogenes</i> , <i>S. dublin</i>)	Fetal stomach contents (FSC). Placenta	Fetal lung, liver, gall bladder, kidney, brain, eyelid. Dam vaginal swab, placentome, blood.	Ancillary samples where FSC/placenta unavailable/contaminated.
<i>Neospora caninum</i>	Fetal brain, serum/transudate	Fetal heart. Placenta. Dam/cohort bloods	Fresh brain/placenta for PCR, fixed brain/heart/placenta for histopath
<i>Leptospira Hardjo</i>	Fetal kidney, serum	Dam/cohort bloods	Fetal sample dependent upon lab. tests
BVDv	Fetal ear, spleen, thymus, serum	Fetal kidney. Dam/cohort bloods	Fetal sample dependent upon lab. tests
BHV-1	Fetal liver, serum.	Fetal kidney. Placenta. Dam/cohort bloods	Fetal PCR/histopath preferred tests
Micronutrient deficiencies	Fetal thyroid, liver, heart, rib	Dam/cohort bloods	Thyroid for iodine assay/histopath; liver for selenium assay, heart for histopath; bone for manganese
Gross lesions (e.g. fetal pneumonia)	Affected fetal organ	As required	As appropriate (e.g. bacteriology, histopath)
Genetic congenital defect	Fetal muscle	Dam hair follicles	Test for infectious teratogens also (e.g. BVDv, SBV)

*Standard and ancillary testing protocols are dependent upon local lab SOPs. Bacteriology/mycology (culture, stains, wet preps) and serology are generally routine tests for sporadic cases while other tests (e.g. histopath, PCR, FAT, IHC, micronutrient, DNA assay) can be added for multiple losses or at the discretion of the pathologist. Maternal vaccinal status affects use and choice of serology tests.

Standard abortion package

Be guided by your local laboratory about which samples they prefer to use routinely for each test ('standard abortion package') and which tests are non-routine (e.g. PCR, histopathology). While for sporadic cases the basic sampling package may suffice (Table 3), in abortion storms, tiered sample escalation may be advised as it provides the option of sampling, storing and testing as deemed necessary. Increasingly, genomic tests are being developed for developmental disorders which require specialist sampling, e.g. hair follicles.

Photo-documentation

Photo-documentation can be useful for inexperienced practitioners and for unusual lesions. In future practitioners may be able to use digital imaging technologies to enhance their PME yield, as currently occurs on North American feedlots (remote digital PME).

Sample submission

If samples are collected on a day when the laboratory is closed store the samples for culture, serology and histopathology in a fridge (4°C) and those for PCR in a freezer (-20°C). Practitioners need to be cognisant of postal regulations pertaining to packaging and labelling for biological substances. To facilitate processing of your samples in the receiving laboratory, complete their submission sheet and submit with the samples.

Examining the placenta

If the placenta has not yet been expelled at examination, collect a sample of the retained placentomes or a vaginal swab. A normal placenta at term weighs approximately 5kg, has 75-125 red cotyledons and has thin, translucent intercotyledonary tissue that sometimes contains adventitious placentation. Placentitis may manifest as discoloured, necrotic, exudative cotyledons and opaque, erythematous, thickened, oedematous intercotyledonary tissue. *submit three abnormal cotyledons/inter-cotyledonary tissue samples*

Ideally three abnormal cotyledons/inter-cotyledonary tissue samples should be submitted (preferably macroscopically abnormal and uncontaminated) for histopathological and microbiological examination (Gram smear, MZN, culture, PCR).

CAUSE-OF-DEATH

Diagnosis rates in aborted and stillborn fetuses are generally between 20 to 50% (Wheelhouse et al., 2015) and 30 to 75%, (Mee, 2015), respectively. The more carcasses that are examined the higher the herd diagnosis rate. In aborted fetuses the causes of death are often attributed to events which occurred days or weeks before foetal death so few cause of death lesions will be grossly visible; microbiological sampling is more important. However, in stillborn calves the cause of death is more likely to be periparturient-related, hence gross examination can often reveal more than laboratory testing (Mee et al., 2013). Foetopathogenic infections (Table. 4) and dystocia (abnormal calving) continue to be the most important diagnosable causes of bovine abortion (Clothier and Anderson, 2106) and stillbirth (Mee, 2015), respectively. Co-mortality is not uncommon in stillbirths and should be considered.

Table 4. Detection of infectious abortifacients in Irish cattle (DAFM, 2014)

Organism	Fetuses (%)
<i>Leptospira Hardjo</i>	7.5*
<i>Trueperella pyogenes</i>	6.1
<i>Salmonella dublin</i>	6.0
<i>Bacillus licheniformis</i>	3.6
<i>Neospora caninum</i>	3.5*
<i>Listeria monocytogenes</i>	2.6
<i>Aspergillus</i> spp	0.8
Other bacterial and fungal spp.	17.5
BVDv and BHV	NR
No agent identified	52.4**

NR=not recorded; *not all fetuses are tested for Lepto (fetal ELISA) and Neospora (fetal ELISA +/- histology); ** estimated as not all samples tested for Lepto and Neospora; Anon. (2015)

Diagnosis not reached (DNR)

The common reasons for DNR are diagnoses not attainable from PME, poor PME technique, insufficient, poor quality or incorrect sample submission and inadequate laboratory tests. In the case of aborted fetuses and 'unexplained stillbirths' non-infectious and non-dystocial causes are likely to be a major reason for DNR. While DNR may appear to a client or a practitioner as a failure of PME, it can be viewed as a successful rule-out of common causes of foetopathy.

TIME-OF-DEATH

Fetuses which die before birth will have varying degrees of autolysis; corneal opacity, excess body cavity transudate, decomposed organs (especially kidneys, liver, spleen and brain), haemoglobin imbibition, flaccid musculature, subserosal and subcutaneous serosanguinous oedema/emphysema and atelectatic lungs. Autolytic lesions develop within approximately 12 hours of death in utero and become more advanced over time. Fetuses which die during birth will not have signs of autolysis and may have signs of breathing (partial lung inflation), bradytocia (localised peripheral oedema) or traumotocia (trauma lesions with haemorrhage). Perinates which die shortly after calving will not have signs of autolysis and will have signs of breathing (partial or complete lung inflation, tracheal froth, umbilical thrombi), possibly attempting to stand or standing (worn eponychia, especially hind) and consuming colostrum (colostrum in abomasum).

An epidemiological approach to herd problem-solving

Simon More & Luke O'Grady

UCD School of Veterinary Medicine

University College Dublin, Belfield, Dublin 4, Ireland

a. Investigating individual cases

'Making a diagnosis' is a central tenet of clinical veterinary medicine, allowing veterinarians to recognise a disease, and to assign this disease label to a case that presents with particular clinical or pathological characteristics. The diagnostic process draws on the education of veterinarians, but also their experience and judgement. Ultimately, assigning a diagnosis allows for ease of communication with colleagues along with the selection of appropriate and effective therapeutic actions.

Radostits et al. (2000) describe a number of different methods used by veterinarians when making a diagnosis on an individual animal, with the two most common generally being:

Pattern recognition, that is, recognition of the disease syndrome, after comparison with previous cases. This approach is common among experienced clinicians

Hypothetico-deductive reasoning. Initially, multiple plausible diagnostic hypotheses (differential diagnoses) are generated, based on presenting clues. Then, the clinician asks questions and conducts clinical examinations, to test (support or discount) each hypothesis. The process of hypothesis and deduction continues until one hypothesis is preferred over all others.

These approaches are used, often unconsciously, in combination or interchangeably depending on the clinical circumstances and prior experience.

A further more time-consuming approach is 'the key abnormality method', a five step process including sequential determination of:

- The abnormality of function present,
- The system or body as a whole or organ affected,
- The location of the lesion within the affected system or organ,
- The type of lesion, and
- The specific cause of the lesion.

b. Moving from the individual to the herd

As with individual animal medicine, 'making a diagnosis' is also a central tenet of herd health investigations. A correct herd-level diagnosis is generally needed, before proceeding to recommendations for appropriate herd-level strategies for control and prevention.

It is common, and understandable, that clinicians use familiar diagnostic methods during herd health visits; essentially, the same diagnostic method for herds as they would normally do for individuals. Using the two methods most commonly applied to individuals, there would generally translate into the following herd-level approaches to diagnosis:

Comparison with best-practice. Using this approach, the investigation includes a detailed review of farm practices relevant to this case, with the clinician (perhaps subconsciously) comparing practices on the affected farm with what they would view as best-practice. This can be thought of as a herd-level adaptation of 'pattern recognition', where deficiencies in comparison to 'good' farms form the diagnosis, e.g. mastitis problem due to suboptimal post milking teat disinfection. Remedying these deficiencies often forms the basis of action for improvement, e.g. ensuring all steps of the 10 point plan for mastitis control are in place.

Differential diagnoses, being a herd-level adaptation of 'hypothetico-deductive reasoning'. Using this approach, a series of plausible differential diagnoses are generated, typically based on initial

questioning, clinical examination of problem animals to give herd-level clues, to then perform hypothetico-deductive reasoning. Often this requires the use of additional diagnostic testing to identify the single most-likely hypothesis, e.g. investigating a problem of calf diarrhoea to identify the causal pathogen. This approach is then used to employ known efficacious controls relevant to the diagnosis.

These two approaches either in isolation or in conjunction, may often be used effectively to investigate herd problems. However, there are some problems with this direct translation of these diagnostic approaches. Farms are complex places, certainly a collection of individuals, but overlaid with additional layers of environment, management, feeding etc. There are particular challenges associated with each of the two suggested methodologies:

Comparison with best practice. This approach relies on a comprehensive understanding of all of the farm activities, which can be very time-consuming. It is important to recognise that perception of best-practice with vary between clinicians, influenced by many factors including clinical experience. Logically, therefore, lists for improvement (based on perceived differences between the affected farm and best-practice) will also vary between clinicians. Further, using this approach in isolation, it is challenging to prioritise the list for action, i.e. to identify those actions that, if addressed, would make the greatest difference with respect to the problem under investigation. This is especially true if the list is extensive, and can often lead to "fix everything" recommendations.

Differential diagnoses. This approach is of greatest use in simple cases, with a single disease process. However, an evaluation of differential diagnoses is of limited assistance in complex cases, e.g. those with multiple overlapping disease processes (Radostits et al., 2000) or where multiple pathogens, some possibly incidental, are identified during diagnostic testing.

c. An epidemiological approach to herd problem-solving

In many ways, epidemiology is quite unlike many other veterinary disciplines. In the traditional disciplines that we are most familiar, such as physiology, microbiology or pathology for example, the focus is at the level of the individual, the organ or the cell, seeking a clear understanding of processes of normality or disease. The key question here is 'how', to help us to better understand the 'why'? In contrast, epidemiology focuses on populations, underpinned by principles and utilising methods that seek to allow us to be solid conclusions from apparently uncontrolled situations. Here, the key questions are 'where', 'when' and 'whether', providing perspectives on the 'why' to complement those provided by the traditional disciplines. As such, epidemiology is a science that is well suited to herd investigations.

In a herd investigation, we generally focus on one or more of the following three questions:

- The cause, including what are the key points in the causal pathway that has resulted in the problem?
- Control, what can be done to stop it? What potential actions can be taken to effectively break the causal pathway?
- Prevention, what can be done to prevent it happening again? What actions can either remove causal factors or reduce the frequency or impact of their occurrence?

The issue of cause is particularly important in a herd investigation, noting that there is rarely a single cause; rather our interest will generally focus on causal pathways, on drivers and on risk factors. Herd problem-solving is typically conducted where performance is substantially less than the farm goals that were set.

Before proposing an epidemiological approach to herd investigations, it is critical to first distinguish performance and activity:

Performance refers to the output, or what is achieved. With respect to

milk quality, this could relate to the bulk milk somatic cell count achieved during a defined period of time

In contrast, activity refers to processes, or what was done. With respect to milk quality, this could include in-parlour practices such as stripping, teat dipping and cow segregation, the blanket use of dry cow therapy, the regular servicing of the milking machine etc

The epidemiological approach to herd investigation builds on the previously outlined strategies by introducing relevant epidemiological principles and methods. It seeks to overcome the challenges, as highlighted previously, when using diagnostic methods such as 'comparison with best-practice' or 'differential diagnoses'. The approach provides a structured and generic investigative framework, allowing clinicians to focus their efforts as quickly as possible during the investigation.

Step 1: Focusing on performance

During this initial stage of the investigation, it is critical to focus on performance, rather than activity. Indeed, any thoughts or concerns regarding activities on the farm should initially be ignored.

Firstly, the problem needs to be framed in terms of performance, for example, 'an increase in calf mortality', 'an increase in SCC', or 'an increase in the incidence of lameness'.

Then, a case definition is developed to enable cases to be identified and counted (for example, 'a calf that died during the last month', 'a cow with at least one SCC reading greater in 200,000 cells/mL during the current lactation', 'a cow with a lameness score of 3 or greater'). The case definition is very important, as it enables the investigator to count cases, and to distinguish cases from non-case (or control) animals. A numeric focus such as this is not a surprise, noting that epidemiology is a science underpinned by numbers.

Finally, these data allow a clinician to calculate simple measures of case frequency and of epidemiological association. With this information, it is possible to determine whether patterns (systematic differences between cases and controls) may be present, either in time, in space and between different animal groups.

If patterns are present (for example, 'a seasonal pattern of presentation is apparent', or 'there appears to be an increased risk among first lactation animals as compared with older cows'), these can be considered as clues, providing a sound basis for the development of multiple plausible causal pathways. In other words, these clues are used, where feasible, to rule in plausible hypotheses, and to rule out hypotheses that do not feasibly match the patterns observed.

Step 2: Investigating relevant farm activities and examining case animals

During step 2, the clinician only considers those activities that have the potential to plausibly contribute to any of the hypotheses identified in step 1. In other words, step 1 assists greatly, allowing considerable focus during the on-farm investigations. This is in contrast to the 'comparison with best-practice' method mentioned previously, where all aspects of herd activities need to be scrutinised.

During this step, a process of hypothetico-deductive reasoning is used, as outlined previously. Guided by the hypotheses developed during step 1, the clinician identifies relevant farm activities and seeks further information about each, through questions and by other means. In addition, clinical examinations and sample collection may be conducted, generally restricted to case animals, to test (support or discount) each hypothesis. The process of hypothesis and deduction continues until one hypothesis is preferred over all others.

In further contrast to the 'comparison of best-practice' method, using an epidemiological approach to herd problem-solving can assist in prioritising actions, specifically those actions that are likely to make the greatest difference, if enacted.

Step 3: Developing recommendations, and communicating these to farmers

Ultimately, for clinicians it is critical to be seen to add value beyond generic disease control practices. With individual animal cases, the treatments and solutions often lay in the hands of the clinician. In contrast, the resolution of most herd issues resides with the actions of the client. Therefore to be an effective herd clinician, communication and facilitating behavioural change is key. The role of the clinician in the herd scenario should be to facilitate understanding, to present potential solutions based on tackling the causal factor(s), and to help to prioritise actions.

In contrast, when using either the 'comparison with best practice' and 'differential diagnoses' herd diagnostic approaches, there is a limited ability to prioritise in the face of complexity. This prevents decision making based on the ranking of likely casual factors and the efficacy or efficiency of interventions. In addition, there is a danger that recommendations will be 'cherry-picked' by the farmer, leading to clinician frustration when key recommendations are not followed.

d. Summary

This epidemiological approach is used routinely by farm animal clinicians within University College Dublin. It is considered a generic and robust process. While it incorporates 'comparison with best practice' and 'differential diagnoses' investigative strategies, the initial focus on performance evaluation is closely aligned to 'the key abnormality of function' approach to individual animal cases. Whereas using the key abnormality of function approach is often regarded as unnecessarily complicated and time consuming in individual animal cases, the use of an epidemiological approach is easily justifiable during herd investigations as the ultimate outcomes are highly reliable in the face of complexities inherent in a herd-level focus.

Genomic selection for animal welfare and environmental impact traits in dairy cattle

Jennie Pryce

Department of Economic Development, Jobs, Transport and Resources and La Trobe University, Bundoora, VIC 3083, Australia

Abstract

Genetic selection has led to phenomenal rates of genetic gain in milk production traits. However, from the mid-1990s, it was recognised that narrow breeding goals, focused on production traits, had negative consequences for fitness traits, impacting on animal welfare. The most obvious was the deterioration in female fertility, which has been observed worldwide. Since then, breeding goals have been extended and realised selection responses for traits such as fertility show that genetic selection can improve even low heritability traits. More recently, there has been a surge of interest in selecting for health traits and traits associated with resources, such as feed efficiency and methane emissions, even though the collection of these phenotypes may be expensive and only possible in small populations. In fact all these traits are ideal candidates for genomic selection where the basic requirement is a population that has genotypes and phenotypes (either on the individual or its progeny). Genotypes and associated phenotypes are used to create a reference population to calculate genomic prediction equations that can be applied to cows or bulls that are genotyped but do not have phenotypes. The opportunities to apply genomic selection to traits related to welfare and environmental impact are abundant, for example, feed efficiency, methane emissions and common health disorders, such as mastitis resistance, lameness and ketosis have large enough accuracies to be used in selection decisions. One option is to customise future breeding goals to include appropriate traits for the prevailing management and environmental conditions. For example, selection for heat tolerance is of great importance in emerging (and many existing) dairy regions. Genomic selection offers exciting prospects for genetically improving scarce and expensive to measure traits, such as those associated with dairy welfare and resource usage.

Traits under single gene control

In cattle breeding, there are many conditions that are determined by single genes, for example red coat colour is controlled by a recessive gene, so an animal has to have two copies of the recessive allele to be red in coat colour, if *r* denotes the recessive allele, *rr* genotypes will be red and *Rr* and *RR* will be black. Conditions such as polled follow a dominant mode of inheritance, in other words, individuals that are either heterozygous (one copy of the gene) and homozygous (two copies) are polled. There are also genetic diseases that have the same mode of inheritance, such as CVM, BLAD and DUMPS in Holsteins. Most of these disease are the result of reasonably recent (rare) mutations. For example complex vertebral malformation, or CVM can be traced to two former elite Holstein sires, because of their widespread use, the sires appeared on both sides of the pedigree of affected calves (Agerholm et al., 2001). Conditions such as these diseases highlight the importance of managing rates of inbreeding, which arises as a result of the co-occurrence of common ancestor(s) in maternal and paternal pedigrees.

Selecting for quantitative traits

Many of the traits that we deal with in animal breeding are polygenic in their genetic control. This means that the genetic architecture is often complex, involving many loci. Although it may be obvious that quantitative traits, such as height or weight are controlled by multiple loci, many diseases are also complex in their genetic architecture.

Genetic improvement programmes in cattle breeding have largely focused on quantitative traits. The models devised to do this analysis

have historically used pedigree information to devise an animal's genetic merit based on its ancestry and relationships with other animals in the dataset. Best linear unbiased prediction (BLUP) is the method that commonly does genetic analysis of cattle and has been the cornerstone of genetic evaluation programmes almost universally. Add to this the ease of exchange of genetic material worldwide in dairy cattle breeding, principally using AI, but also embryos and genetic improvement in many traits has been made.

Genomics

Genomic selection refers to selection decisions based on genomic breeding values (Meuwissen et al., 2001). The way it works is that a genomic reference population is assembled, typically genotyped bulls with large numbers of progeny. A genomic prediction equation is then calculated from the reference population by looking for associations between phenotypes and dense genetic markers that are approximately equally spaced across the entire genome. In cattle a variety of marker panels are used, the ones that are commercially used for genomic selection in have around 50,000 genetic markers. The genomic breeding values are calculated as the sum of each of the genotypes multiplied by its respective effect on a trait, thereby potentially capturing most of the genes that cause differences between animals in the traits of interest. This prediction equation can then be applied to individuals that are genotyped, but have no phenotypes. Therefore, the genetic merit of an individual can be calculated as early as birth and therefore selection decisions can be made earlier in life than traditional progeny-test approaches.

Genomic selection is now used routinely in many countries for genetic evaluation of traits that already have an estimated breeding value derived from a combination of pedigree and phenotype information (Spelman et al., 2013). The advantage of genomic selection for these traits is that the rate of genetic gain is accelerated by 40-50% (Spelman et al., 2103).

Selection objectives

Historically, the rationale to extend breeding goals to include new traits focussed entirely on their impact on farmer profitability. However, breeding goals are now becoming more complex in order to meet challenges set by consumers and society (Boichard and Brochard, 2012, Martin-Collado et al., 2015). Over the last couple of decades we have already seen a rapid evolution in the number of traits that are available for farmers to select on. Almost without exception these breeding values rely on large amounts of field data that are freely available through current recording systems, such as: milk production, calving records, insemination dates, pregnancy test outcomes, health records and culling dates. Common current breeding objectives in dairy cattle include: milk production traits, conformation, mastitis resistance through somatic cell count, longevity, calving ease, female fertility and workability traits.

The best way to ensure that all (measured) traits that contribute to profitability are included in selection decisions is to select the sires of the next generation using the local national selection index, examples include: EBI in Ireland, BPI in Australia, BW in New Zealand, PLI in the UK, NM in USA etc. An index is constructed by calculating appropriate weights for each of the breeding values included in the index. Historically the weights were calculated solely using economics, however more recently there has been interest in including farmers desires in the calculations e.g. (Martin-Collado et al., 2015).

Although selection for fertility, health, longevity etc has been practiced for over 30 years in Nordic countries (Heringstad and Østerås, 2013), for most countries, it was only from the 1990s that serious attention was given to selecting to improve other traits. Through the research happening at this time, it became clear that the observed deterioration in fertility and health traits was partly genetic therefore requiring a genetic solution.

Fertility

Fertility is one of the most important traits in dairy cattle breeding and the remarkable decline in fertility observed through the 1990s and part of the 2000s is partly attributable to narrow selection goals that focused on selection for milk production traits. Heritability estimates of traditional fertility traits are generally low (<0.1); yet selection for fertility can lead to worthwhile changes, because the trait is highly variable (Pryce and Veerkamp, 1999, Berry et al., 2014b). Between 40 and 64% of the deterioration in fertility is believed to be due to genetics VanRaden et al. (2004), (Berry et al., 2014b).

Pryce et al (2014b) used data collated by the World Holstein Federation to show that phenotypic calving interval appears to have reached a plateau by 2007. Between 1990 and 2000 calving interval increased "worldwide" by 1.25d/year phenotypically (Pryce et al., 2014b). The story of cow fertility has led to valuable lessons have been learnt by dairy geneticists in the dangers of narrow breeding goals. In addition to sustaining selection on fertility, welfare and disease resistance traits in particular are becoming key areas where breeding values are being developed for future breeding goals.

Health traits

In 1988, the first major review of data recording opportunities and consequently breeding strategies to improve production diseases was published (Emanuelson, 1988). However, since then computerised farm recording has led to a large increase in data available on these traits and consequently studies on genetic parameter and breeding value estimation.

Mastitis

One of the most important diseases in dairy production is mastitis. Selection to improve this trait is already being practiced in many countries through selection for reduced somatic cell count (SCC). Cell count can be quantified from routinely assessed milk samples and has a genetic correlation of around 0.7 with mastitis (Mrode and Swanson, 1996). However, several studies have shown that selection for mastitis directly is more effective than relying solely on predictor traits (such as SCC) (Heringstad et al., 2006, Egger-Danner et al., 2012, Gaddis et al., 2014). Currently the Nordic countries, Austria, Germany, Canada and France use clinical mastitis records in genetic evaluations (Egger-Danner et al., 2015).

In addition to SCC, other predictors of clinical mastitis could be used to increase the accuracy of breeding values. Examples include conformation (Lund et al., 1994), electrical conductivity from automated milking systems (Norberg, 2005) and lactate dehydrogenase which is a potential biomarker for mastitis (Friggens et al., 2007).

Lameness

Feet and leg issues are common reasons for culling in dairy cattle (Egger-Danner et al., 2015). Selection to reduce lameness has historically focused on conformation of feet of legs, as this is routinely recorded by breed societies and many countries already calculate breeding values for these traits (Table 1). However, the accuracy of breeding values for claw health or resistance to lameness increased when claw health data is included (Koenig et al., 2005).

Metabolic diseases

Metabolic disorders, such as ketosis, displaced abomasum, milk fever and tetany are disturbances to one or more of the metabolic processes in dairy cattle. Under-recording and difficulty in diagnosing subclinical cases are amongst the reasons why there is growing interest in using easily measurable predictors of metabolic diseases, either recorded 'on-farm' by using sensors and milk tests or 'off-farm' using data collected from routine milk recording (Pryce et al, 2016 in preparation).

Heat tolerance

Increases in ambient temperature, humidity, air flow and radiation exceeding the comfort zone are known to lead to heat stress in dairy cattle. This can lead to reduced appetite, production and compromised health and fertility. As with other traits, genetics offers a permanent and cumulative way to alleviate heat stress. Short-term heat stress an animal's appetite and therefore reduction in yield is often observed. It is possible to evaluate at what temperature-humidity load cows are affected and there is genetic variation in this trait. The heritability of heat tolerance around 0.11 (Nguyen et al., 2016; in press).

Feed efficiency and methane emissions

Feed is a major component of variable costs associated with dairy systems and therefore of great interest in dairy breeding objectives where the objective is to maximise profitability. However, it is expensive to accurately measure individual feed intakes on large numbers of cows. However, this makes feed efficiency an ideal candidate for genomic selection. As feed efficiency is so expensive to measure it is a good trait for international collaboration to establish an even larger reference population. In fact, (de Haas et al., 2012) combined dry matter intake phenotypes from Dutch and UK cows with Australian heifer phenotypes and found that the accuracy of genomic prediction was 5.5% higher when a multi-country reference population was used, compared to single-trait models. Since then, there has been further international collaboration through the global Dry Matter Initiative (gDMI) to build an even larger reference population (Berry et al., 2014a). The accuracy of genomic prediction is highest when a combined reference population is used (de Haas et al., 2015). Currently only Australia and the Netherlands have breeding values for feed efficiency that include feed intake data in their calculation.

Selection for reduced methane emissions is a growing area of interest. Recently, using a portable air sampler and analyser unit to measure methane emissions on 3,121 cows from 20 herds, Lassen and Løvendahl (2016) estimated that the heritability of methane emissions varied between 0.16 (s.e. 0.04) and 0.21 (s.e. 0.06). The genetic correlation with fat and protein corrected milk was high indicating that selection for production will lead to an improvement (reduction) in methane emissions. Selecting on traits that improve the efficiency of farm systems e.g. milk yield, residual feed intake and longevity will also have a favourable effect on overall emissions (Wall et al., 2010).

Conclusions

Selective breeding can be used to improve traits associated with welfare and climate change, ranging from traits controlled by single genes to those with complex genetic architecture.

Narrow breeding goals (i.e. selection for milk production only) leads to a deterioration of welfare related traits e.g. dairy cow fertility.

There is sufficient genetic variation in traits associated with animal welfare, such as health traits to make genetic progress in these traits feasible.

The most practical way to make genetic progress is to use the local national selection index e.g. EB1 in Ireland, BPI in Australia, BW in New Zealand, PLI in the UK, NM in USA etc.

Bovine viral diarrhea viruses (BVDV) and their cousins the HoBi-like viruses:

Multi symptom, multi host, multi-tasking pathogens

Julia Ridpath

Ruminant Diseases and Immunology Research Unit

National Animal Disease Center

ARS/USDA

Ames, IA

Introduction

The term bovine viral diarrhea (BVD) has come to refer to a diverse collection of clinical presentations that include respiratory, enteric and reproductive symptoms accompanied by immunosuppression. While the majority of cases are subclinical in nature two forms exist, mucosal disease and hemorrhagic syndrome, that are associated with clinically severe disease and high mortality¹. BVD may be caused by one of three different species of bovine pestivirus, bovine viral diarrhea virus 1 (BVDV1), BVDV2 and HoBi-like viruses²⁻⁵. Regardless of species, isolates may exist as one of two biotypes, cytopathic and noncytopathic. Isolates of the noncytopathic biotype, but not the cytopathic biotype, can establish persistent infections, which are the result of infection of the fetus during the first one third of gestation^{6,7}. While the primary hosts of these three viral species are cattle natural and experimental infections of a wide range of domestic and free ranging hosts are possible^{8,9}. All three species have been found as contaminants of fetal bovine sera. Control measures include detection and culling of persistently infected animals and vaccination^{10,11}. At present commercial vaccines and diagnostics are based on BVDV1 and BVDV2 strains and have limited efficacy for the detection and control of HoBi-like virus strains^{12,13}.

History and clinical presentation of BVD

The first reports of what subsequently was named BVD started with a call made by Dr. Francis Fox to a farm on the outskirts of Ithaca, New York in March of 1946 1996

¹⁴. Subsequent outbreaks on 5 additional farms, resulted in the recognition of "an apparently new transmissible disease of cattle"¹⁵. The presentations observed in these 5 farms reflect the mix of enteric, respiratory and reproductive disease that marks BVD outbreaks to this day. Immune depletion was observed regardless of clinical presentation. In the same year a disease outbreak was reported in Canada that had a number of similarities to the cases in New York¹⁶ (Childs, 1946), with exception that lesions were more severe, morbidity was lower and mortality was 100%. In retrospect the Canadian outbreak is recognized as the first published report of mucosal disease (MD)¹⁷. MD is a unique form of BDV that is the result of superinfection of an animal, persistently infected (PI) with a noncytopathic bovine pestivirus, with a cytopathic bovine pestivirus. While previous researchers had theorized that persistent infection was a lifelong consequence of fetal exposure, it wasn't until 1984 that persistent infections were reproduced under controlled conditions⁷. Those studies demonstrated that persistent infection could only be established if fetal exposure, in cattle, occurred prior to 125 days gestation and that persistent infection occurred following infection with noncytopathic viral isolates but not cytopathic viral isolates. It was also noted that PI calves had variable outcomes⁷. Some died as neonates while others survived the neonatal period but were stunted and suffered from poor thrift. Still others, while normal in appearance and surviving into adulthood, had a significantly higher rate of mortality due to respiratory or enteric disease compared to non-infected animals. It was noted that PI cattle succumbing to MD were infected with both cytopathic and noncytopathic BVDV¹⁸. Subsequently it was demonstrated experimentally that MD was the result of PI cattle being superinfected with a cytopathic BVDV^{18,19}.

Another form of BVDV appeared in North America in late 1980's and early 1990's²⁰⁻²³. The clinical presentation, which came to be known as hemorrhagic syndrome (HS) included severe pyrexia, bloody mucoid diarrhea and death within two weeks of initial clinical symptoms. It was found that the pestivirus isolates associated with HS belonged to a newly recognized species of pestivirus called BVDV2⁴. BVDV1 and BVDV2 strains differ both genetically and antigenically²⁴⁻²⁶. While several BVDV2 isolates were identified that caused HS^{4,27,28}, it was noted that infection with the majority of BVDV2 strains did not cause HS²⁹⁻³². In addition to a difference in the range of virulence following acute infections, the BVDV2 species has a slightly more restricted global distribution than the BVDV1 species, as BVDV2 isolates have not been detected in cattle in Australia.

Recently a new species of pestivirus associated with BVD, variously known as HoBi-like virus, bovine viral diarrhea virus 3 (BVDV-3) or atypical bovine pestivirus, has emerged. First described as a contaminant in a batch of fetal bovine serum imported into Europe from Brazil³³, these viruses were subsequently isolated from dairy cattle in Thailand³⁴, Brazilian water buffalos³⁵, aborted fetal bovine tissues samples from Brazil³⁶, calves suffering from respiratory disease in Italy² and cattle suffering from fever, diarrhea, and/or respiratory distress in Bangladesh³⁷. Surveillance studies in India detected more HoBi-like virus strains than BVDV1 and BVDV2 strains³⁸. Similar to BVDV1 and BVDV2 strains, noncytopathic HoBi-like virus strains can establish persistent infections^{5,39} and persistent infection can lead to mucosal disease⁴⁰.

The complete host range of HoBi-like virus is unknown, but under experimental conditions it can infect cattle, sheep, goats and pigs⁴¹. Because the earliest isolates of HoBi-like viruses were from samples collected from water buffalo and the two regions (South American and Asia), where HoBi-like viruses seem to have the highest prevalence, have significant populations of water buffalo it has been hypothesized that HoBi-like viruses in cattle result from a spill over from water buffalos. Of the three species of virus that cause BDV, HoBi-like viruses are the most geographically restricted with reported animal isolations in only three continents, Asia, Europe and South America.

Host range

Although most commonly associated with the infection of domestic livestock, based on natural and experimental infections, BVDV1, BVDV2 and HoBi-like viruses can replicate in a wide range of domesticated and free ranging ruminants (Table 1). The impact of bovine pestivirus replication in non-bovine hosts is not well documented. Bovine pestivirus infection of swine has significant economic impact in China^{42,43} and the detection of persistent infection in alpaca's in the US led to changes in health screening of alpaca for shows and breeding being instituted by the alpaca industry⁴⁴. The lack of regular surveillance programs, challenges in sampling wild populations, and scarcity of tests and vaccines specific for non bovine species compound the difficulties in detecting and controlling pestivirus infections in free ranging ruminants.

If infection of cultured cells is taken into consideration, the host range is even larger^{45,46}. In a survey of cell lines in the American Type Culture Collection (ATCC)⁴⁵ it was found that cell lines from cattle, sheep, goat, deer, bison, rabbit, and domestic cat were contaminated with BVDV. Attempts were made to experimentally infect 14 swine, rabbit, hamster, cat, dog, monkey, and human cell lines available from the ATCC that had been found free of virus in this survey. All swine cell lines, and most rabbit and some cat cell lines, became infected with BVDV while hamster, human, dog, and certain rabbit and cat cells were refractory to BVDV infection. It was assumed that the contaminated cell lines detected in the ATCC became infected due to the use of contaminated fetal bovine serum.

Table 1 Host range

Bovine pestivirus species	Primary host	Detected in free ranging wildlife species	Experimental in vivo Infections	Found as contamination in cell lines
BVDV1	Cattle	Bovidae, Cervidae, Leporidae, Antilocapridae, Camelidae	Bovidae, Cervidae, Leporidae, Antilocapridae, Camelidae, Suis	Bovidae, Cervidae, Leporidae, Suis, Felidae
BVDV2	Cattle	Bovidae, Cervidae, Antilocapridae, Camelidae	Bovidae, Cervidae, Leporidae, Antilocapridae, Camelidae, Suis	Bovidae, Cervidae, Leporidae, Suis, Felidae
HoBi-like	Cattle and Water buffalo	Not detected	Bovidae, Suis	Not detected

Contamination of reagents

The theorized introduction of HoBi-like viruses into Europe and the contamination of the ATCC via contaminated fetal bovine serum (FBS) highlight the problems resulting from bovine pestivirus contamination of reagents. A review of the literature between 1975 and 2012 revealed reports of the testing of 667 lots of commercial fetal bovine serum for infectious BVDV⁴⁷. The percentage that of lots that tested positive varied between 4% and 100% with an average of 29% containing infectious BVDV virus. Testing of 115 commercial lots for BVDV genomic RNA reported between 1996 and 2012 ranged from 46% to 100% positive with an average of 79% positive. This review of the literature noted that while BVDV is inactivated by gamma irradiation (30 kGy; equivalent to 3 Mrad), it was reported that the use of gamma irradiation failed to eliminate BVDV from a small percentage of FBS lots. Use of contaminated FBS in tissue culture propagation may give rise to BVDV infected cell lines and contamination of vaccines. As part of an international cooperative effort directed towards the improvement of the quality of medicines, the European Directorate for the Quality of Medicines of the Council of Europe (EDQM) organized a scientific symposium on pestivirus contamination of bovine sera in 2001. Based on the discussions at this meeting the (EDQM) organized a scientific symposium on pestivirus contamination of bovine sera in 2001⁴⁸. Based on the discussions at this meeting the committee for medicinal products for veterinary use (CVMP) revised their guideline on requirements and controls applied to bovine serum used in the production of immunological veterinary medicinal products to reads as follows;

4.3.3.2. Tests to detect Bovine Viral Diarrhoea virus

These tests should be carried out, a first time, before the inactivation treatment to assess the infectious titre of Bovine Viral Diarrhoea Virus potentially present to ensure it is below the level that has been shown to be effectively inactivated in the validation tests for inactivation treatment. Secondary tests should be performed after the inactivation treatment at which time no virus should be detected in the final serum batch (CPMP, 2003).

These guidelines are recommendations not regulations and it is not clear to what extent commercial FBS suppliers and biologics manufacturers follow them.

Similar to BVDV1 and BVDV2 viruses, HoBi-like viruses continue to be found as contaminants of commercial FBS to the present^{49,50}. Currently there are no recommendations or requirements testing for commercial FBS for HoBi-like viruses. Further, the sensitivity of HoBi-like viruses to gamma irradiation has not been established and standard testing methods are not recognized.

Conclusion

BVD eradication programs have been successfully enacted in some countries using control measures such as testing for and culling PI cattle and vaccination¹⁰. However, these programs do not address of the control of HoBi-like viruses in endemic regions or strategies to prevent the introduction of HoBi-like viruses into non-endemic regions. The diagnostic tests and vaccines used in current BVDV control programs were designed based on BVDV1 and BVDV2 strains and have limited efficacy against HoBi-like viruses. Further, current control programs focus only on domestic cattle and do not take into account the circulation of viruses that cause BVD in non bovine domestic species and free ranging species.

The proceedings from the International Symposium Bovine Viral Diarrhea Virus A 50 Year Review included this quote from one of the founding fathers of BVD research, Dr. Francis Fox of Cornell University;

“After observing and dealing with this disease for 50 plus years, I conclude that BVD is an interesting, intriguing, unpredictable, and most challenging disease which can quickly bring about financial disaster to the herd owner and apparently is going to be with us for some years to come.”(Fox, 1996)

It appears that Dr. Fox was not just a preeminent scientist but something of a seer as well. Just as he predicted, BVD is still with us and despite progress is still causing significant problems to this day.

Managing Dairy Cow Health Through Nutrition

Dr. John Roche

DairyNZ, Private Bag 3221, Hamilton, New Zealand 3240
Abstract

Nutrition's role in dairy cow health is, primarily, in the prevention of metabolic disease and in the management of chronic inflammation. Metabolic disease and associated premature deaths are a significant cost to dairy businesses, not to mention a considerable labour burden during already busy periods and, increasingly, an animal welfare concern. More than 90% of metabolic diseases occur during the transition between pregnancy and early lactation, and a mature cow is 6-times more likely to die during the month after calving than at any time during lactation. Diseases can be primarily divided into energy balance (EBAL)-related diseases, such as ketosis and fatty liver, or mineral-related diseases, such as milk fever, although most metabolic diseases are inter-related. Historical recommendations were to ensure cows were in positive EBAL before calving. More recent research results, however, indicate that if cows are a body condition score ≥ 3.0 (5-point scale), as is recommended, a positive EBAL before calving increases the risk of EBAL-related metabolic diseases and milk fever, and increases the concentration of inflammatory mediators circulating in blood. Instead, these cows should be managed to consume 80-100% of their daily metabolisable energy requirements during the two to four weeks before calving. In comparison, however, thinner cows (i.e., at a body condition score < 3.0) are at a low risk of EBAL-related metabolic diseases; if in negative EBAL before calving, these cows have higher concentrations of inflammatory mediators circulating in blood post-calving. Ideally, therefore, these cows should be managed to consume 100% of their metabolisable energy requirements before calving. Our increased understanding of the aetiology of these diseases will help aid in their prevention.

Introduction

Nutrition's role in dairy cow health is, primarily, in the prevention of metabolic disease and in the management of chronic inflammation. The majority of metabolic health disturbances occur between calving and three to four weeks (wk) post-calving. For example, Godden et al. (2003) reported that 14.5% of dairy cows culled in Minnesota exited the herd during the first 30 days (d) in milk, while Compton (personal communication) reported a three- to six-fold greater risk of death during the first month post-calving than at any other stage in the inter-calving period. It is generally accepted, therefore, that nutrition management during the weeks preceding calving is critical to reduce the risk of peripartum metabolic dysfunction, chronic inflammation, and exit from the herd during early lactation (Roche et al., 2013a) involving coordinated changes across multiple tissues and an enormous increase in nutrient requirements. Failure to transition successfully can result in reduced DM intake, milk production, delayed oestrus, failure to conceive and increased incidence of metabolic and infectious diseases, many of which are inter-related. Modern technologies have enabled the measurement of transcriptional changes in genes involved in multiple biochemical pathways across the transition period, enabling a better understanding of the implications of management and nutritional changes on cow health and productivity. Most recent research efforts have focussed on the association between pre-calving energy intake and postpartum health and productivity, with a general recognition that the positive relationship between pre-calving energy intake (and relevant circulating metabolites.

The six to eight wk transition between pregnancy and lactation (i.e., the transition period) has been extensively investigated and the major metabolic hallmarks characterising healthy and functionally compromised cows have been well described in numerous reviews (Goff and Horst, 1997; Drackley et al., 2001) ketosis, retained placenta, and

displacement of the abomasum-occur within the first 2 wk of lactation. The etiology of many of those metabolic diseases that are not clinically apparent during the first 2 wk of lactation, such as laminitis, can be traced back to insults that occurred during early lactation. In addition to metabolic disease, the overwhelming majority of infectious disease, in particular mastitis, becomes clinically apparent during the first 2 wk of lactation. Three basic physiological functions must be maintained during the periparturient period if disease is to be avoided: adaptation of the rumen to lactation diets that are high in energy density, maintenance of normocalcemia, and maintenance of a strong immune system. The incidence of both metabolic and infectious diseases is greatly increased whenever one or more of these physiological functions are impaired. This paper discusses the etiological role of each of these factors in the development of common diseases encountered during the periparturient period.”.

Many other reviews have summarised the diverse array of nutritional management strategies proposed to minimise metabolic dysfunction and the risk of disease in the periparturient period (Grummer, 1995; Horst et al., 1997)

Calcium transfer to the fetus in late pregnancy and the subsequent transfer of calcium to milk represent the greatest challenges to calcium homeostasis in adult animals. The adaptation of the maternal calcium homeostatic mechanisms is the result of a complex interplay between calcitropic hormones and the tissues, intestine, bone, and kidney, responsible for providing the large amounts of calcium needed to support fetal skeletal growth and lactation. In this review, we will discuss general calcium homeostasis followed by a review of the specific adaptations required by the human, rat, and cow to meet fetal and lactational demands for calcium. Finally, we will review what is known about the regulation of calcium transfer from the plasma to the milk.”.

(Grummer, 1995; Horst et al., 1997. Nevertheless, despite decades of trialling numerous nutritional strategies to maintain dry matter (DM) intake (DMI) and control the mobilisation of body stores of fat (i.e., body condition score; BCS), calcium, and, to a lesser extent, protein in early lactation, the incidence of metabolic disease and impaired performance remains high in both intensively managed confinement and more extensive pasture-based dairy production systems.

The purpose of this review is 1) to integrate recent research results with previous knowledge of transition cow metabolism and nutrition, and 2) to offer new insights into key elements of successful management of the transition cow, with particular emphasis on preventing energy balance (EBAL)-associated diseases, such as ketosis, and milk fever.

Historic advice – the need to feed: Steaming up transition cows!

Boutflour (1928) reported that, in his opinion, the “most serious limiting factors” influencing the cow's ‘yield of milk’ included “the neglect of the preparation of the cow for her lactation period”. In so doing, he defined the ‘Transition Period’ as a critical phase of the cow's lactation. He recommended that cows be fed an increasing amount of ration during the six wk before calving, with DMI of 4 to 6.5 kg DM, in addition to maintenance, required during the two wk before calving. Such a high pre-calving DMI became known colloquially as “steaming up” or “fitting” the cow, with the intention being to ensure cows were in positive EBAL before calving.

In support of the ‘steaming up’ concept, Hutton and Parker (1973) reported that cows that were fed to gain 0.7 kg live weight (lwt)/d during the four wk before calving produced 10-15% more milk during the first eight wk of lactation, when compared with cows fed to maintain lwt. More recently, Bertics et al. (1992) reported that cows force-fed through a rumen fistula before calving and into early lactation had lower concentrations of liver triacylglycerol (TAG) on the day of calving and produced 10% more fat-corrected milk during the first four wk of lactation when compared with cows that underwent a reduction in DMI before calving. Support for a

positive EBAL before calving also came from a positive relationship between pre-calving blood fatty acid (NEFA) concentration and post-calving disease incidence (Dyk, 1995). Therefore, it was concluded, that it is important to maintain or increase DMI before calving to prevent the net release of adipose tissue. These studies supported the need for a 'steaming up' ration before calving.

The peripartum profile of change in dry matter intake

In general, the "drive to eat" increases with energy requirements (Roche et al., 2008). A major exception to this rule appears to be the pre-partum dairy cow, whose DMI is reported to decline during the weeks preceding parturition (Bertics et al., 1992). 28 days before parturition, to examine the effect of ration energy level on the ad libitum consumption of energy in relation to requirements. During 25 days following parturition, 0, 2, 4, and 4 cases of left displacement of the abomasum occurred in the four ration groups, respectively. The mean daily dry matter intake 28 days prepartum did not differ significantly ($P < .05$) despite the increasing energy requirements for foetal growth and lactogenesis (Bell, 1995) decreased peripheral tissue glucose utilization, increased fatty acid mobilization from adipose tissue, and, possibly, increased amino acid mobilization from muscle. Within 4 d of parturition, mammary demands for glucose, amino acids, and fatty acids are severalfold those of the pregnant uterus before term. Even unusual postparturient increases in voluntary intake cannot satisfy this increased nutrient demand. Therefore, rates of hepatic gluconeogenesis and adipose fat mobilization are greatly accelerated. Concomitant changes in amino acid metabolism include increased hepatic protein synthesis and, possibly, decreased amino acid catabolism, and increased peripheral mobilization of amino acids. Insulin resistance in adipose tissue and muscle, developed during late pregnancy, continues postpartum; adipose lipolytic responsiveness and sensitivity to adrenergic agents are increased postpartum beyond their levels during late pregnancy. Before parturition, these homeostatic adjustments may be coordinated with lactogenesis by increased secretion of estradiol and prolactin. Their amplification and reinforcement at and soon after parturition may be regulated mostly by somatotropin.",

In recognition of this pre-calving decline in DMI and the putative need to have cows in positive EBAL, diets were formulated to increase energy density during the month before calving, primarily through reducing the forage to concentrate ratio.

However, the pre-calving decline in DMI is not universal. Roche (2006) and a failure to do so is reported to have negative implications on postcalving DMI (Grummer, 1995 reported no decline in DMI in the wks preceding calving in dairy cows consuming fresh pasture and hay, Coppock et al. (1972) 28 days before parturition, to examine the effect of ration energy level on the ad libitum consumption of energy in relation to requirements. During 25 days following parturition, 0, 2, 4, and 4 cases of left displacement of the abomasum occurred in the four ration groups, respectively. The mean daily dry matter intake 28 days prepartum did not differ significantly ($P < .05$) reported that DMI only declined pre-calving when concentrates exceeded 25% of diet DM, and Douglas et al. (2006) fat supplementation decreased dry matter (DM reported no decline in DMI pre-calving in cows restricted to 80% of energy requirements; however, in the latter study, DMI of cows offered unrestricted access to TMR declined during the three wks pre-calving. In fact, recent research from von Keyserlingk's group at University of British Columbia indicates that the pre-partum decline in DMI is associated with an impending malaise (e.g., metritis, ketosis) and not impending parturition, per se (Huzzey et al., 2007). If true in all cases, feeding activity could be a prognostic indicator of impending ill health. Taken together, these studies indicate that the reported decline in DMI before calving is not a 'natural' event associated with impending parturition.

The 21st century and a paradigm shift in thinking – are we killing the modern cow with kindness?

Despite the compelling evidence presented earlier to support the practice of 'steaming up' cows pre-calving, a closer examination of the results reveals inconsistencies. For example, in the study by Bertics et al. (1992), the high DMI cows in the force-fed group had 50% greater plasma NEFA circulating in blood and almost 100% greater plasma β -hydroxybutyrate (BHB) at 2 wk post-partum when compared with the low pre-calving DMI group. Considered in its entirety, therefore, Bertics et al. (1992) results indicate an increased risk of EBAL-related diseases with increased pre-calving DMI. These results do not support increasing DMI or diet energy density as the solution to the malaise indicated by elevated pre-partum NEFA (Dyk, 1995). Furthermore, studies designed to increase NEFA release before calving by restricting energy intake (Holtenius et al., 2003; Douglas et al., 2006; Dann et al., 2006) fat supplementation decreased dry matter (DM; Loor et al., 2006; Roche et al., 2005; Roche, 2007) 8.2, 10.0, or 11.0 kg/d of pasture dry matter per cow for 27 +/- 9.6 d precalving. This equated to 1.3, 1.9, 2.4, and 2.6% of body weight (BW; not including the conceptus weight provided no evidence of greater post-partum disease. In fact, cows that were feed-restricted for several weeks before calving had increased capacity for hepatic gluconeogenesis and β -oxidation, reduced hepatic TAG accumulation, and a reduced risk of milk fever and ketosis (Douglas et al., 2006; Loor et al., 2006; Roche et al., 2015) fat supplementation decreased dry matter (DM.

Recent research results indicate that cows overfed before calving have an inferior metabolic profile after calving (Douglas et al., 2006; Loor et al., 2006; Holtenius et al., 2003; Roche et al., 2005, 2015) fat supplementation decreased dry matter (DM. Overfed cows have higher NEFA and BHB concentrations, a lower post-calving DMI, and a greater negative EBAL during the two wk post-calving. This is a critical period, as 30-50% of BCS mobilisation occurs during this time (Roche et al., 2007) 352 daily BCS records across 3,209 lactations in 1,172 cows from a research herd in New Zealand. Mean daily BCS (scale 1 to 10 and factors that exacerbate NEFA release from adipose tissue are likely to increase the risk of metabolic disease. In addition, however, overfed cows have lower blood calcium on the day of calving (Roche et al., 2005, 2015; Roche, 2007) 8.2, 10.0, or 11.0 kg/d of pasture dry matter per cow for 27 +/- 9.6 d precalving. This equated to 1.3, 1.9, 2.4, and 2.6% of body weight (BW; not including the conceptus weight, implying an increased risk of milk fever.

To further complicate transition cow management, Roche et al. (2015) reported an interaction between pre-calving BCS and pre-calving DMI; the interaction implies that the benefit of the pre-calving feed restriction is through alleviating the risk of EBAL-related diseases associated with over-conditioning. The results indicated that:

- if cows with a BCS ≥ 3.0 (5-point scale) are restricted to between 80 and 100% of daily metabolisable energy requirements during the month before calving (i.e., a slight negative EBAL), they have superior profiles of metabolic and inflammatory-state (i.e., lower circulating concentrations of acute phase proteins and markers of inflammatory state) during the critical first two wk post-calving.
- cows with a BCS ≤ 2.5 , but in a similar negative EBAL to the high BCS cows before calving had an inferior inflammatory-state profile post-calving, even though plasma NEFA and BHB were lower.

This interaction is consistent with the large increase in the risk of EBAL-associated metabolic diseases with increasing calving BCS (Roche et al., 2013b). Garnsworthy and Topps (1982) were among the first to propose that historical recommendations for BCS were too high for modern dairy cows that were prone to excessive NEFA release in early lactation and, as a result, at a greater risk of EBAL-related diseases immediately post-calving (for review, see Garnsworthy, 2006). Combining a higher than optimal BCS (i.e., >3.0) with a positive EBAL before calving (i.e., steaming up) results in a failure to initiate the metabolic pathways

required for NEFA oxidation in the liver and increases the accumulation of liver TAG (Loor et al., 2006). In so doing, transition cows are at an increased risk of other metabolic diseases and premature mortality.

Summary – EBAL-related diseases

The aetiology of metabolic diseases is complex. However, two particular factors appear to interact to pre-dispose cows to a greater risk of EBAL-related disorders. The amount of NEFA released from adipose tissue increases and DMI declines post-calving with greater pre-calving BCS (Garnsworthy, 2006; Roche et al., 2009). This effect of BCS on the metabolic state of the transition cow is exacerbated by cows consuming energy in excess of requirements before calving. Releasing NEFA from adipose stores before calving primes the relevant tissues for NEFA oxidation, particularly the liver. As fatter cows (i.e., ≥ 3.0) release more NEFA during the first two wk post-calving, they are at an increased risk of TAG accumulation and associated liver dysfunction, which reduces the capacity of the liver for gluconeogenesis (Loor et al., 2006), increases the risk of ketosis, and exacerbates the peripartum chronic inflammation. Because of this, if cows are BCS ≥ 3.0 , they should be managed to consume approximately 80% of their requirements during the two to four wk pre-calving. If the diet is primarily long-chop forages (e.g., grass silage, hay, or fresh pasture), this restriction can be managed through reducing feed allowance (Roche et al., 2005, 2015; Janovick and Drackley, 2010) 8.2, 10.0, or 11.0 kg/d of pasture dry matter per cow for 27 \pm 9.6 d precalving. This equated to 1.3, 1.9, 2.4, and 2.6% of body weight (BW; not including the conceptus weight). However, if the diet is a finely chopped mixed ration, restricting DMI could increase the risk of displaced abomasum. Instead, a reduction in the energy density of the ration through the inclusion of straw or low digestibility hay or silage will facilitate the reduction in energy intake. Cows that are thinner than BCS 3.0 are at a low risk of EBAL-associated metabolic disorders and should be fed to requirements.

The Role of Veterinarians in Udder Health Programs

Pamela L. Ruegg, DVM, MPVM

University of Wisconsin, Madison, USA

Introduction

Throughout the world, the structure of dairy farms is evolving. In 2015, milk production in the E.U. increased by about 5%, with Ireland experiencing the greatest increase in wholesale milk deliveries. In the U.S., consolidation of dairy farms has occurred at a rapid pace. In 2012, dairy farms containing more than 500 cows comprised only 6% of all U.S. herds, yet produced 63% of total U.S. milk output. As the dairy industry has globalized, the trend toward larger dairy herds is accelerating and has influenced the role of veterinarians. On larger dairy farms, cows are managed in groups, workers are specialized and farm owners often have apparently free access to a variety of technical services provided by agribusinesses. These changes in farm structure are influencing demand for veterinary services. Historically, most dairy veterinarians provided a "herd health" program that focused on managing fertility (Derks et al., 2012) and pregnancy examination has been the primary reason for routine herd visits. However, many aspects of reproductive herd health programs are now being performed by paraprofessionals (Mee, 2007b) and the loss of a reason for veterinarians to routinely visit farms can result in decreased opportunities for consultation on other topics. The objective of this paper is to review the current role of veterinarians in udder health programs and propose a framework for enhancing that role to meet the evolving needs of dairy farmers and consumers.

Perceptions and Reality of Veterinary Engagement in Udder Health Programs

The purpose of dairy herd health programs is to prevent animal disease, improve animal well-being, reduce treatments and help ensure profitability of the dairy business. Most research about herd health programs consistently indicates that relatively few veterinarians offer comprehensive udder health programs. Only 24% of dairy farmers who enrolled in a milk quality program in Wisconsin, indicated that they routinely used their veterinarian to plan milk quality programs (Rodrigues et al., 2005a) and 3-4 years after completing the, only 38% of the farmers continued working with veterinarians on udder health (Hohmann and Ruegg, 2012). In a separate survey, most dairy veterinarians indicated that they spent <10% of their professional time actively working to improve milk quality (Rodrigues and Ruegg, 2004). In England, the most common response of veterinarians was that they did not provide regular veterinary advice about mastitis control to any farms but many indicated that they occasionally provided some monitoring. In The Netherlands, udder health was listed as the 3rd priority for herd health and about 50% of dairy farmers believed that veterinarians were not aware of or were ignoring their goals for herd health (Derks et al., 2012).

In contrast to reproductive health programs, implementation of an udder health program often requires input from other farm advisors and application of problem solving rather than clinical skills. Veterinarians frequently overemphasize possessing technical knowledge over marketing and communication skills (Kristensen and Enevoldsen, 2008). Barriers to improvement of milk quality are primarily related to motivation and implementation rather than lack of technical knowledge or skills (Rodrigues and Ruegg, 2005, Jansen et al., 2010, van den Borne et al., 2014). One reason may be that veterinarians typically have similar personality types that tend to overemphasize logical, organized and practical approaches to the world (Johnson et al., 2009). These traits are important for clinical decision making, but are not skills that are generally associated with individuals who are effective at convincing farmers to invest in udder health programs.

Numerous surveys have demonstrated that veterinarians and dairy farmers often have very different perceptions of each other's goals

(Kristensen and Enevoldsen, 2008, Lievaart et al., 2008, Lam et al., 2011, Hall and Wapenaar, 2012, Derks et al., 2013). In comparing responses of farmers and veterinarians about components of a herd health program, virtually all responders agreed that reproductive health monitoring is part of a herd health program, while fewer farmers included routine monitoring of udder health (Lievaart et al., 2008). Many farmers are price sensitive and value efficient use of time, thus programs that are perceived to be time consuming and provide low financial returns are often discontinued (Derks et al., 2013). Without appropriate presentation and marketing of udder health programs, only the most motivated farmers will routinely participate.

Opportunities for Veterinarians to Engage in Udder Health Program

Reasons that veterinarians fail to engage in reproductive herd health programs include lack of demand, failure to justify cost lack of confidence and competence, lack of desire to proactively engage with other service professionals and lack of financial incentives (Mee, 2007a). These same reasons likely apply to veterinary engagement in udder health programs, however there are plenty of reasons for veterinarians to increase involvement. It is well known that mastitis has a profound impact on farm productivity and animal welfare. The occurrence of mastitis reduces milk production, increases the amount of milk discarded and premature culling and costs (Fetrow, 2000). Veterinary involvement in udder health programs is often limited to reacting to increased bulk tank SCC, but there are tremendous opportunities for veterinarians to provide more services. Antibiotic use in livestock is an increasing concern and control of mastitis accounts for the majority of antibiotics used on dairy farms, (Pol and Ruegg, 2007, USDA, 2008, Saini et al., 2012, Gonzalez Pereyra et al., 2015). Increased involvement of veterinarians in oversight of treatment protocols for mastitis is a logical starting point and this opportunity can serve as the platform for beginning more comprehensive involvement in consultative services.

While some countries require veterinary supervision of antibiotic treatments (Lind et al., 2012), in many regions, administration of treatments for mastitis are the responsibility of farm personnel and veterinarians are involved only when a case becomes life-threatening (Richert et al., 2013). While prescribing drugs is usually a veterinary responsibility monitoring compliance and efficacy is often neglected. Ideally, the veterinarian collaborates with farm workers to develop and evaluate farm specific treatment protocols. The veterinarian also has a role in ensuring that treatment protocols are effectively delivered. On large farms, the veterinarian can be an important resource for training farmers to collect milk samples and to properly administer treatments. The veterinarian can also provide oversight of on-farm laboratories used to guide treatment decisions. While other service providers often have specialized knowledge about nutrition, breeding and milking, only veterinarians have specific training in immunology, mammary physiology, pharmacology and microbiology. These unique skills should be leveraged by veterinarians to provide services that facilitate implementation of an annual udder health plan.

Components of an Annual Udder Health Plan

Veterinarians have long been encouraged to deliver comprehensive herd health programs that include monitoring performance, prescribing corrective actions and evaluation of outcomes. The challenge is finding time to provide and be compensated for these services. When aspects of an udder health program are considered, there is a long list of areas of potential veterinary involvement (Table 1). However, veterinarians are not considered the first source of expertise for some components and may compete with other service providers who do not appear to directly charge for their services. Among all potential components of an udder health program, use of effective treatment protocols that ensure justifiable use of antibiotics is the area that is most unique to veterinary expertise and veterinarians need to increase involvement

Table 1. Potential components of an annual udder health monitoring plan (adapted from Ruegg, 2011).

Potential areas of involvement for veterinarians	Components of Annual Udder Health Plan	Examples of compliance indicators or key performance indicators ¹
Ensuring justifiable use of antibiotics	Identification and training of farm workers authorized to administer antibiotics	Signed training documents for authorized farm workers
	Development, review and revision of all treatment protocols	Review of all authorized treatment protocols based on assigned expiration dates
	Monitoring compliance with treatment protocols	Number of days of treatment and milk withhold
	Regular review of efficacy of antibiotics used in mastitis treatment protocols	Recurrence of CM, SCC reduction, proportion of cases requiring treatment changes, etc.
	Drug residue avoidance	Monthly review of withholding days for milk and meat of cows treated in month
Monitoring clinical mastitis	Incidence rate	<25 new cases per 100 cows per year
	Recurrence within 60-90 days	<20% of incident cases
	Distribution of severity scores,	50% mild, 35% moderate, <15% severe
	Case fatality rate	<2% of clinical cases
	Identification of chronicity	<5% of cows milking on <4 ¼
Monitoring subclinical mastitis	Bulk Tank SCC	<250,000 cells/mL
	Prevalence (% > 200,000 cells/mL)	<15% of cows
	Incidence (cows with SCC>200,000 cells/mL for 1 st time in lactation ^a or change from previous month ^b)	<5 ^a -8 ^b % new SCC>200,000 cells/mL ²
	Prevalence in early lactation (measured at 5-40 days in milk)	<5% of 1 st parity cows with SCC>200,000 cells/mL
	Prevalence in late lactation (measured in last month before dry off)	<30% of cows with SCC>200,000 cells/mL
Bacteriological quality of bulk milk	Total bacterial count (TBC), Laboratory pasteurized count (LPC), Preliminary incubated count (PIC), Coliform count	<10,000 cfu/mL TBC; <200 cfu/mL LPC; <10,000 cfu/mL (PIC); <100 cfu/mL (coliform count)
Use of appropriate diagnostic methodologies	Bulk tank culture	0 cfu of Strep ag, Staph aureus & Mycoplasma bovis
	Culture guided selective treatment for clinical mastitis (on-farm or in-veterinary clinic)	see guide at milkquality.wisc.edu
	Diagnosis for selective dry-cow therapy programs	Targeted culture-based programs
	Appropriate use of molecular technologies	Guided use of PCR and other technologies
Preventive programs	Monitoring hygiene	<20% udder hygiene scores "dirty"
	Monitoring milking protocols	Prep-lag time of 60-120 seconds; >90% of teats adequately covered with post-dip
	Monitoring bedding/pasture quality	Review bacterial counts of bedding
	Management of dry cows & heifers	SCC in early lactation (see above)

¹Suggested KPI for some indicators are available online: <http://milkquality.wisc.edu/> ; ²depending on method of calculation

in this area. The development of an annual udder health plan that is initially structured to focus on this aspect is one mechanism for local veterinarians to engage producers in managing udder health.

A Framework for Prioritizing Veterinary Engagement in Udder Health Programs

The focus of udder health programs should be on prevention of new infections and a comprehensive udder health program will require inputs from all relevant advisors and is best implemented in a team-based setting. Farmers consistently indicate that they value teamwork and goal setting (Kristensen and Enevoldsen, 2008, Lind et al., 2012) and participation in team-based herd management programs have been shown to result in benefits to dairy farmers (Rodrigues and Ruegg, 2005). Leadership of an annual team-based udder health plan is an obvious mechanism for veterinarians to leverage the strengths of various consultants while maintaining focus on ensuring justifiable use of antibiotics. Annual udder health plans should be formulated in a team-based setting and include reasonable goals that are arrived at by consensus of team-members, a limited number of actions and methods to evaluate the results of the actions, assignment of responsibilities to team members to accomplish actions and target dates to meet and evaluate progress. Simple forms (on paper, tablets or laptops) are often useful for guiding the programs (forms are available online: <http://milkquality.wisc.edu/programs/milk-money/>). Experience with a team based milk quality program has shown that this simple process can be successful in encouraging adoption of best management practices and increasing involvement of veterinarians in udder health programs (Rodrigues et al., 2005a, Rodrigues et al., 2005b). The process is simple and can initially require as little as 4 hours of management time per year. A team of advisors agrees to meet to formulate the plan, and schedules a series of 1 hour meetings that are focused strictly on udder health (depending on herd goals, the interval between meetings may range from 1-4 months). At the first meeting the team sets initial goals for udder health and assigns actions to various team members to complete. At least one goal should be permanently reserved for development, implementation and evaluation of treatment protocols that limit unnecessary use of antibiotics. On many farms, the first step in development of a treatment plan is to ensure that an appropriate mastitis recording system. A review of antibiotics usage should be performed and practitioners should periodically recheck which antimicrobials are being used and if farmers are in compliance with governmental regulations. At subsequent meetings, the action list is reviewed and people are held accountable for completion of their tasks. Farmers who participated in this type of program indicated that they increased consultation with their veterinarian about milk quality from 20% (before program) to 84% (at the end of the 4 meetings) (Rodrigues and Ruegg, 2005). Analyses of herds that completed a team based goal oriented program indicated that this method can result in rapid improvement in milk quality (Rodriguez and Ruegg, 2005).

Conclusion

Veterinarians have an opportunity to increase involvement in udder health programs and the development of an annual udder health plan is a mechanism that can be used to overcome barriers to veterinary engagement. There are a number of key influencers who often work with dairy farmers in various aspects of udder health and rather than compete to provide services, the formation of a team-based udder health plan can leverage knowledge, skills and resources to better serve the farmers needs. The development of a team-based annual udder health plan also provides a mechanism for veterinarians to evaluate treatment protocols to ensure that all antibiotic usage is justifiable and appropriate.

Small ruminants: opportunities for improved production efficiency to sustainably meet the needs of the world's human population for food.

Neil Sargison

Easter Bush Veterinary Centre

Roslin Midlothian EH25 9RG

The role of small ruminant farming

Having evolved as selective browsers in resource poor, semi-arid or humid ecological environments, goats are generally more robust and efficient than other domestic ruminant species in their metabolism and tolerance of poor quality and potentially toxic nutrients and conversion into food products. Sheep have evolved to be particularly well adapted to convert short herbage to milk or meat. Different small ruminant breeds and production systems have been developed to suit local resources in seasonally biodiverse environments throughout the world. Small ruminant production is, therefore, suited to both advanced agricultural systems on productive, fertile land, and to environments that are harsh, or seasonally deficient in energy, nitrogen, phosphates, water and organic manure. Small ruminants are consequently adaptable to meet global needs for food security and have potentially important roles in improving the health and wellbeing of the rural poor in their marginal environments.

Small ruminants are generally better suited to enhancing the livelihoods of the poor than cattle and buffalo. This is due to their manageable size, relatively low maintenance requirements per unit of product, low capital investment cost, short generation interval and ease of marketing of animals and products, hence suitability as short-term economic reserves. Small ruminant farming is widely portrayed to be a solution to the challenge of achieving socioeconomically and environmentally sustainable global food security in the face of effects of population growth, urbanisation and affluence, vulnerability to climate change and the hitherto irresponsible agricultural use of drugs and chemicals.

Efficiency of small ruminant farming

Global small ruminant farming is generally inefficient and unsustainable with reference to utilisation of the world's finite resources to provide food for its burgeoning human population. There is a fundamental requirement to meet the daily nutritional requirements of farmed livestock for maintenance, before any nutrients can be converted into food for human consumption. Consequently, inefficiently produced animals must digest and metabolise more nutrients than efficiently managed counterparts to produce the same yield of meat or milk product. Inefficient production is generally uneconomic and not conducive to achievement of good states of animal welfare, hence unsustainable and socially unacceptable. Furthermore, inefficient farming causes environmentally unsustainable levels of greenhouse gas production, arising from the level of forestomach microbial digestion per unit of food produced.

The economic potential of commercial small ruminant farming in developed agricultural systems and the role of small ruminants in alleviating poverty in seasonally resource-limited regions are frequently not realised. This situation pertains despite advances in animal breeding and genetics, sustainable husbandry and animal health management. Failure to translate research and development into efficient utilisation of natural resources in target environments must be investigated and addressed before small ruminant farming can be exploited as a solution to the challenge of socioeconomically- and environmentally-sustainable global food security.

Ecological impact of small ruminants

Small ruminant farming has contentious ecological effects, such as alteration of natural flora caused by their characteristic selective short grazing or browsing behaviour. In scenarios such as those where small ruminants subsist on unimproved natural herbage with low levels of management intervention, this has the potential to result in environmental degradation. Conversely, in some managed goat herds and sheep flocks, this selective feeding behaviour affords opportunities to create suitable environments for other animal species, for example enabling synergistic co-grazing with cattle or creating environments suited to wildlife conservation management. Co-grazing small ruminants with other domestic herbivores in this manner can have both positive and negative animal health benefits. Selective clearance of vegetation by goats may help to limit the habitats of arthropod disease vectors; while goats may act as reservoirs of infection for more susceptible co-grazed hosts, or vice versa. Furthermore, in some agricultural production systems, small ruminants may be an ecologically-friendly source of manure. The net ecological impact of small ruminant farming on other forms of agricultural or biological production, wildlife and the natural environment are poorly understood. Better knowledge of consequences of interactions within whole farming systems is required to define and address sustainability in these regards.

Genetic improvement and technological advance

To-date, the main focus of attention to redress failures of small ruminant production to meet global needs for food security has been upon genetic improvement, through breed replacement, breed crossing heterosis and, or, within breed selection. This has been in conjunction with the development of new technologies, such as automated electronic recording systems, or reproductive management tools. In some regions small ruminant breeding schemes have been established, or proposed, to provide farmers with genetically improved animals capable of larger litter sizes and, or, faster kid growth. Arguments have been made to identify and genetically capture beneficial *de novo* mutations, thereby editing genes to engineer animals that are tolerant of diseases for which pharmaceutical or vaccine control is ineffective or unsustainable. These technologies will inevitably become essential, as over the next 50 years, the United Nations Sustainable development Forum predicts that the world's farmers will need to produce more food than in the past 10,000 years combined. However, genetic and genomic progress will only succeed if the animals are first kept alive and productive by applying scientific health planning principles to integrate animal genetic selection with good nutrition, husbandry and disease management.

Genetic improvement has had a major impact on pig and broiler poultry industries. Similar levels of improvement in small ruminant genetics are theoretically possible allowing small ruminant farming to become sustainably efficient within 10 years. However, the based on the slow rate of improvement over the past 10 years, the likelihood of achieving this potential is low. Genetic improvement in pigs and broiler poultry has been successful because it has been matched by appropriate nutrition and animal health management. However, precise nutritional and animal health management is easier in closed groups of housed pigs and poultry fed on cereal based rations, than it is in pastorally managed small ruminants.

The solutions to some of the nutritional and animal health constraints to achieving the potential of genetic improvement are known. Hence there is an opportunity for improvement in global food security through the development of impactful educational tools for small ruminant farmers or keepers and their veterinary advisors. However, the practical application of solutions to many nutritional management and animal health constraints are unknown, requiring applied research to allow the potential of genetic improvement to be realised.

Planned small ruminant health management

Unsatisfactory commonplace scenarios, such as high rates of neonatal mortality, poor growth rates and poor reproductive performance in small ruminants can only be addressed by applying scientific health planning principles to identify and manage primary causes, rather than the common practice of deferring to pattern recognition. Veterinary medicine must change to allow the scientific application of health planning approaches to address suboptimal production in groups of animals within the overall context of their environment, husbandry, management and contemporary agriculture. A fresh perspective of targets, management and disease control is needed, with a focus on the responsible and sustainable use of remedies, rather than a dependence on pharmaceutical treatments.

The iterative principles of planned animal health involve: i) benchmarking the productivity of the animals against tangible targets; ii) identifying any constraints and rationally investigating their causes; iii) ensuring that the most appropriate remedies are used efficiently, based on assessment of the individual circumstances; iv) evaluating the response to and cost benefits of whatever management or remedies are employed; and v) continuing to monitor and address issues repeating the process as indicated to ensure ongoing improvements in productivity and welfare. As the process advances, the application of state-of-the-art scientific research becomes increasingly important in ensuring optimal efficient and sustainable productivity.

Having determined that key small ruminant production indices do not meet pragmatic system-specific targets, the next step is to identify the primary constraints. This involves: i) evaluation of the problem history; ii) assessment of environment; iii) examination of animals; and iv) the use of practical diagnostic tests and expertise in the interpretation of their results. However, the global availability of appropriate and validated tests for the diagnosis of many important production limiting diseases is limited. This can be a barrier to useful disease diagnosis, regional and national disease surveillance, the development of disease management strategies, and national and international disease control programmes. Accurate diagnosis is important to allow the application of state-of-the-art scientific research, for example concerning genetic selection for production and resistance to disease constraints, or use of genomic markers to monitor and develop treatment, management or eradication strategies.

Having first identified primary animal health constraints, the practicality, appropriateness and cost benefits of remedies must be evaluated. It is necessary to determine the balance between the cost of forage production, or labour inputs required to tend animals on free-access herbage, and the nutritional value, while also considering the impact of the animals on the overall ecosystem to which they belong. The response and cost benefits of infectious disease control need to be evaluated.

Small ruminant nutritional management

The primary reason for keeping small ruminants is to convert primary herbage or other crop resources into marketable meat, milk, or fibre products. Hence, inadequate nutritional management has direct effects on economic production efficiency. Inadequate nutritional management has consistently been shown to be a primary obstacle to achieving the genetic potential for production of small ruminants.

The nutritive values of a range of natural herbage and of cultivated crops, are well known and the principles of ration formulation are understood. However, as a general principle, the nutritive value of the ration that is actually fed or ingested is often misjudged due to seasonal variation in the availability of nutrients, poor understanding of the energy cost associated with growing or feeding herbage, or changes in availability as a consequence of urbanisation and other demands on grazing and crop producing land. There is a tendency to compensate for seasonal variations in availability of natural and cultivated herbage through feeding of cereals. However, concentrate feeding induces a reduction

in the pH of the forestomach contents, potentially reducing the efficiency of digestion of primary herbage resources. Similar considerations apply to the growing practice of energy crop by-product feeding. There is therefore a need for better understanding of the nutritive value of herbage that is fed to small ruminants, of the concept of a balanced ration, and of the effects of concentrate feeding on the efficiency of digestion of primary natural nutrient resources.

Undernutrition can weaken host protective immune responses to infectious diseases such as helminth, arthropod and protozoal parasitism, or contagious viral diseases, with indirect consequences on economic small ruminant production efficiency. Conversely, the consequences of poor nutrition are commonly compounded by inadequately managed disease constraints. It is therefore important to recognise the impact of different constraints to production efficiency on each other. For example, diverse problems of high nematode parasite burdens and poor reproductive performance may be consequences of the animals being in poor body condition and negative nutritional balance. Consequently, improving the efficiency of utilisation of seasonally available herbage resources may be a practical approach to addressing parasitological or reproductive problems. This might be achieved by introducing a compact, seasonal lambing or kidding pattern, following the model that is prerequisite for pastoral cattle production. A compact reproductive period further enables targeted disease management, for example helminth control, and targeted grazing and nutritional supplementation management, in line with the global move towards precision livestock farming systems. However, before promoting such a fundamental change in animal husbandry, it is first necessary to understand the seasonal nutrient availability and deficiencies in conjunction with compounding effects of infectious disease threats.

Infectious disease management

Infectious diseases such as lameness, mastitis, respiratory disease, or slow onset causes of ill thrift in adult animals are important constraints to efficient small ruminant farming in many systems. These diseases are generally predisposed to by specific management practices. Hence, addressing the predisposing causes is generally more effective for their control than reliance on antimicrobial drugs. The threat of antimicrobial drug resistance raises concerns about dependence on whole group prophylactic or metaphylactic treatments.

Infectious disease plagues such as foot and mouth, bluetongue and peste des petits ruminants (PPR) are a serious problem in many parts of the world. The solutions to these problems lie in the development and application of rapid diagnostic tests, effective vaccination regimes, or eradication.

Global importance of parasites to small ruminant farming

Eleven of the World Health Organisation's seventeen Neglected Tropical Diseases (NTDs) of humans are parasitic infections (Chagas disease; Dracunculiasis; Echinococcosis; Food borne trematodiasis; Human African trypanosomiasis; Leishmaniasis; Lymphatic filariasis; Onchocerciasis; Schistosomiasis; Soil transmitted helminthiasis; and Taeniasis/cysticercosis). A further NTD is thought to be mechanically spread by parasitic vectors (Tachoma). There is limited evidence to show the net impact of parasitic diseases on small ruminant production. However, parasitic diseases are widely considered globally to be as important in small ruminants as they are in humans, being the foremost animal health constraints to efficient production. Eight of the NTDs are also classified as Neglected Zoonotic Diseases (Echinococcosis; Taeniasis/cysticercosis; Foodborne trematodiasis; Human African trypanosomiasis; Leishmaniasis; and schistosomiasis), demonstrating a direct human health priority to control parasitic diseases in livestock.

Globally diverse climatic conditions provide various opportunities for the survival and development of free living and environmental stages

of a range of arthropod, protozoa and helminth parasites; while large livestock populations and diverse agricultural management enable completion of the parasite life cycles. Consequently, tick, mite, fly, louse and flea infestations all occur commonly in small ruminants. Vector borne diseases, including haemoprotozoa and filarial nematode infections are particularly problematic where warm and humid environmental conditions favour temporary parasites. Protozoal parasite infections such as cryptosporidiosis, coccidiosis and toxoplasmosis are commonplace because intensive and sometimes unhygienic management favour host infection; while seasonally warm and wet climatic conditions, or drinking water supply management are conducive towards oocyst survival. Nematode infections are commonplace where environmental conditions and livestock management result in the development of high infectious larval challenge; and haemonchosis is a major production limiting disease in regions with seasonally warm and wet climates. Trematode parasites such as *Fasciola* spp. and *Dicrocoelium* spp. liver flukes, amphistome rumen flukes and *Schistosoma* spp. blood flukes cause disease in animals kept in environments that favour parasite infection and development in the intermediate hosts. Small ruminants are both intermediate, and definitive hosts to a wide range of cestode parasites including *Taenia* spp and *Echinococcus* spp., and *Monezia* spp., respectively. The principles of sustainable parasite control in the face of changing epidemiology brought about by socioeconomic and climatic changes are, therefore, important with reference to ensuring global food security.

Nematode parasites

Nematode parasites cause significant economic losses to farmers and their keepers in terms of reduced production and treatment costs, as well as being a major welfare issue for the infected animals. *Haemonchus contortus* is arguably the greatest cause of poor production efficiency in small ruminants globally, causing ill thrift, anaemia and death. Gastrointestinal trichostrongyle nematodes such as *H. contortus* have direct life cycles, involving non-parasitic environmental egg, first, second and third stage larvae, and parasitic third and fourth stage larvae, and dioecious, sexually reproducing adults. The biology of these parasites is, therefore, influenced by both environmental and host factors, which must be understood and accounted for when planning for their control.

The aim of all approaches to nematode parasite control is to limit the host challenge to a level, which does not compromise performance or welfare, while at the same time enabling the development of protective immunity. Sustainable nematode control in individual flocks or herds must, therefore, be underpinned by knowledge of the farming system and of the relationship between pasture contamination, availability of infective larvae and the build up of infection in host animals. There has been a tendency to focus on prescriptive approaches to the control of nematode parasites, which are not always founded upon knowledge and understanding of these principles. In fact, given the economic impact of nematode parasites and complexity of the principles underpinning their control, most farmers and small ruminant keepers, worldwide, rely upon the use of anthelmintic drugs in an unsustainable attempt to treat infected animals. Such treatment frequently involves routine prescriptive anthelmintic treatments of individual animals, or mass drug treatment camps.

Current prescriptive approaches to the control of nematode parasites are generally ineffective and inevitably unsustainable. *H. contortus* resistance to benzimidazole, imidazothiazole, macrocyclic lactone drugs is now commonplace, highlighting the need for iterative flock and herd health planning, incorporating evasive nematode control and strategies aimed at slowing the emergence of anthelmintic resistance. The principles of sustainable nematode control in the face of changing epidemiology brought about by socioeconomic and climatic changes are poorly understood. Advances are needed in understanding these principles in small ruminant production systems to address the global need for efficient livestock production. The publication of a high quality

draft *H. contortus* genome and transcriptome affords opportunities to combine veterinary clinical investigation of nematode parasitic diseases with post genomic research to identify impactful solutions to the challenge of sustainable nematode control.

Education

There are many unknown factors with regards to sustainable nutritional management and parasite control, hence a need for applied research. However, in many cases poor production efficiency is caused by simple animal husbandry problems such as poor basic hygiene and colostrum management. The solutions to these challenges are already known, as they are for aspects of nutritional management and parasite control. Hence there is a requirement for the development of tools and systems, such as the 'train the trainer' concept, aimed at translation of knowledge of good animal husbandry, health planning, principles of disease control and mitigation of zoonoses for small ruminant farmers and keepers.

Summary

There are many reasons for the unsustainability of global small ruminant production to meet the requirements of small ruminant farmers and keepers for both subsistence and profit. The principal opportunities for improvement are afforded by integrating animal genetic selection with good nutrition and health management. Genetic selection criteria have tended towards particular traits such as milk production, carcase quality or growth rates, but have often failed to consider the suitability of individual animals to their target environment, with reference to nutritional and disease constraints. Improved animal health not only addresses the issue of food security, but also has obvious socio-economic and environmental benefits and improves human health standards through the control of zoonotic diseases. An integrated approach founded on robust scientific principles is required to apply precision farming methods to combine genetic potential with appropriate feeding strategies and planned animal health management.

Benchmarking Animal Welfare: Engaging producers and improving practice²

Daniel M. Weary³ and Marina A.G. von Keyserlingk

Animal Welfare Program, Faculty of Land and Food Systems,
University of British Columbia, 2357 Main Mall, Vancouver, V6T 1Z4
Canada

Introduction

Our research group has worked for some 20 years to identify methods of improving the welfare of dairy cows. Projects vary depending upon farmer and student interest, funding, etc., but one common feature is that we attempt to address real world problems faced on dairy farms, and provide practical solutions that could be adopted by at least some farms. The unhappy truth, however, is that the gap between study and changed practices on commercial farms can be immense. This failure to get research into practice can be due to a number of factors. Maybe the research question was not really relevant to farmers? Or maybe the researcher has just not worked hard enough to tell farmers about their work and how it might be useful?

We have become interested in developing new ways of closing the gap between science and changed practice on farms. The aim of this paper is to describe one such approach. Below we will argue that 'benchmarking' welfare relevant measures is effective in getting farmers interested in problems, and that this method can lead to changed practices on farms resulting in better lives for the animals. We suggest that benchmarking works because it provides the farmer with real data from their own farm and places this data into context by comparing the results with those of other farms in the same region. We have also found that this approach allows for new conversations between the farmer and the professional team they work with, including their veterinarian. In this way benchmarking may provide veterinarians a new way to get their clients interested in specific issues, and to help their clients develop tailored solutions to the problems.

Lameness is perhaps one of the greatest threats to dairy cow welfare; lameness is painful, long lasting and prevalent. Our group's work on lameness has been closely linked to our research on cow comfort; we believe that by building better barns for dairy cows, barns that are more comfortable for the cows to use, we can reduce injuries on the legs and hooves of the cows, and ultimately reduce the rates of lameness. In many studies using our own research farm we have tested various design and management features to see how these affect cow comfort (e.g. Abade et al., 2015; Winkler et al., 2015), injuries (e.g. Proudfoot et al., 2010; Dipple et al., 2011) and lameness (Hernandez-Mendo et al., 2007; Bernardi et al., 2009). For example, a series of studies have shown that cows strongly prefer lying down in stalls with deep, dry, and well maintained bedding (Tucker et al., 2009; Fregonesi et al., 2007; Drissler et al., 2005). We have also found that cows are motivated to find a comfortable place to stand (ideally a soft, dry standing surface), and that providing a more comfortable standing surface reduces lameness (Bernardi et al., 2009).

At our research farm we have been able to do controlled experiments, showing how specific management and design features can affect comfort, injuries and lameness, but this research does not show if these same factors will improve conditions on commercial farms that face different challenges. To better describe how different factors affect these outcomes on commercial farms we began a program of on-farm research, initially focused on farms in our region (the lower Fraser Valley of British Columbia; Ito et al., 2009; Ito et al., 2010) and then moving to regions within the United States (California and the North Eastern

United States; von Keyserlingk et al., 2012) and China (Chapinal et al., 2014 a), each with different traditions and where farms face different environmental and economic constraints.

Below we review our approach to benchmarking cow comfort on modern commercial dairy farms and how this affects lameness and hock injuries in adult cows.

Lameness

In each of the regions we have examined, we have found that some farms are able to manage lameness remarkably well, with only a small percentage of animals lame, while other farms struggle in controlling lameness, sometime with more half the cows on the farm showing clinical signs of lameness (see von Keyserlingk et al., 2012).

Cows were scored as not lame (gait score of less than 3 on a 1 to 5 scale; Flower & Weary, 2006), clinically lame (gait score greater than or equal to 3), or severely lame (gait score of 4 or 5). Figure 1 shows the results for 121 farms visited. In British Columbia (BC) prevalence of clinical lameness averaged 28%, versus 31% in California (CA) and 55% in the North Eastern states (NE); the prevalence of severe lameness averaged 7% in BC, 4% in CA, and 8% in NE.

Our primary goal in this 'benchmarking' work has been to engage farmers in discussion about lameness. Providing the farmers with data from their own farm, together with averages from other farms in their region, allowed them to identify areas of success and areas where work was still needed. Each farmer was provided a confidential report that they could use (ideally together with their farm staff, veterinarian, hoof trimmer and nutritionist) to develop tailored solutions for their own farm.

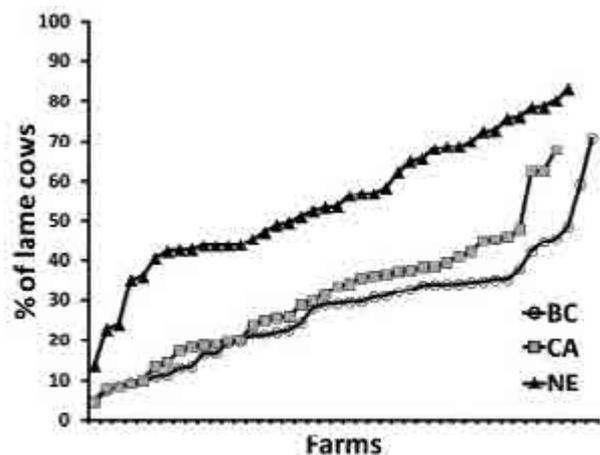

Figure 1. Clinical lameness in British Columbia (BC), California (CA) and the North Eastern US (NE); farms are ranked lowest to highest (from von Keyserlingk et al., 2012).

A second aim of our benchmarking work was to identify housing and management options that lead to lower rates of lameness (Chapinal et al., 2013). Variation in lameness can be explained in part by how barns are designed and managed, but these factors vary among regions due to differences in tradition, barn builders, and availability of materials and bedding. This means that the factors associated with lameness also vary among regions.

For example, in BC we found that the mean prevalence of severe lameness was higher on farms where cows were on mattresses (9% of cows severely lame) versus farms that using deep-bedded stalls (4% of cows severely lame). We also found differences in factors associated with lameness between NE and CA. In NE, where many farms used mats or mattresses with little bedding, the odds of lameness were reduced by half on farms using deep bedding and on farms providing access to pasture for dry cows. In CA, all farms we visited used deep-bedded stalls, and

2 Some of the material in this paper was originally crafted for Research Reports published by the UBC Dairy Education and Research Centre
3 Please direct correspondence to danweary@mail.ubc.ca

almost all of these farms provided outdoor access (typically to a well-bedded dry lot). Likely because of these conditions, rates of lameness were much lower in CA than in NE. Within the CA farms, lameness was lowest on farms where stalls were kept clean (i.e. not contaminated with feces) and on farms that used rubber in the alley leading to the milking parlour. These results suggest that when one limiting factor is addressed (e.g. by changing from mattresses to deep bedding) new factors can be identified (such as the benefits of rubber flooring). In summary, the risk factors for lameness are varied and region specific. For this reason we believe that lameness in particular can benefit from benchmarking programs and the tailored solutions these provide.

Hocks

Unlike lameness, hock lesions are obvious to anyone who cares to look. For example, these can be easily assessed when cows are in the milking parlour providing a clear view of the hind legs. Skin injuries on cattle tend to occur on areas that are in contact with elements of housing, with the most common injuries observed on the knees and hocks. These injuries range from a small area of hair loss to open wounds, and are sometimes accompanied by infection and swelling of the joint.

Cows on each farm were scored for hock condition (lateral surface of the tarsal joint) on a 3-point scoring system; where 1 = healthy hock, 2 = bald area on the hock without evident swelling, and 3 = evidently swollen and/or severe injury. We recorded the % of cows scored with a visible hock injury (i.e. score = 2) and % with severe injury (hock scored = 3).

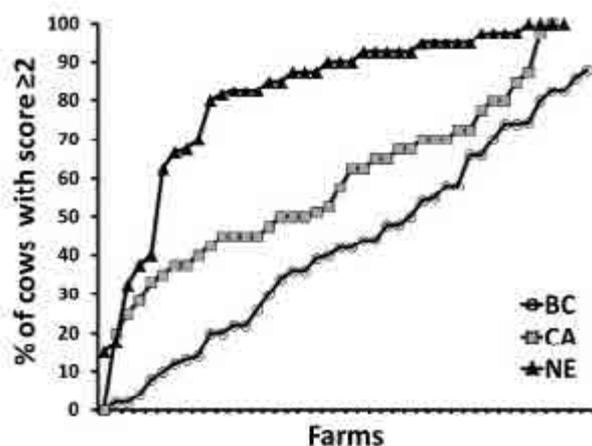

Figure 2. Hock injuries on farms in British Columbia (BC), California (CA) and North Eastern US (NE); farms are ranked from lowest to highest (see von Keyserlingk et al., 2012).

The prevalence of hock injuries varied among regions, from 42% in BC, to 56% in CA, to 81% in NE (Figure 2). The prevalence of severe hock injuries was 4% in BC, 2% in CA and 5% in NE. Our results show that these injuries are all too common, but within each region some producers were able to achieve low levels of hock lesions.

Cows were also recorded for swollen knees (carpal joint); injuries were recorded as present (evidently swollen joint with or without skin damage) or absent. Knee injury was not scored on farms in BC. Swollen knees were rarely observed (less than 1% of cows affected) in CA, but relatively common (23% mean prevalence) in NE.

We know from a series of previous studies, including work in BC more than a decade ago (Weary and Tazskun, 2000), that the risk of hock injuries can be greatly reduced by using deep bedding and that lesions are more common on farms using poorly bedded surfaces like mats and mattresses. This finding helps to explain why lesions were so common

in NE, where poorly bedded surfaces were the norm. Our work in CA and NE has also shown that hock injuries are highly dependent upon bedding management (Barrientos et al., 2013). Most dramatically, in the NE, use of deep-bedded stalls reduced the odds of hock lesions by 95%. Other management practices linked to reduced hock injuries included clean bedding, access to pasture during the dry period, and avoiding the use of automatic scrapers for manure removal. In CA (where all the herds assessed had access to deep bedding) hock injuries were far less common, and farms with well-maintained stalls (i.e. bedding level in the stalls) had the lowest rates. Thus across regions, farms that use well-maintained, deep-bedded stalls had fewer cows with hock injuries. Access to deep-bedded stalls and well-bedded outdoor dry lots also likely explains the low prevalence of cows with swollen knees in CA versus the NE.

Benchmarking programs, like the one we described here, allow producers to compare their performance with averages in their region and provides a basis for informed discussions with professionals involved in farm management, including the herd veterinarian. In the case of hock injuries one solution is obvious – the risk of hock injuries can be much reduced by using deep-bedded stalls.

But does it work?

The ultimate aim of this work is that farmers change conditions and practices to address the problems being benchmarked. We have now begun work to assess how this engagement translates to improved outcomes for the cows. In one recent study, we returned to farms in the NE region of the United States that had been benchmarked approximately 12 months previously (Chapinal et al., 2014 b). This was a convenience sample, consisting of those farmers who were most motivated to have us return to do a re-assessment. Often this was because they had changed housing or management in some way that they perceived would be helpful, so their responses should not be taken as representative. However, among these farms the improvement was impressive. Lameness rates improved on 13 of the 15 farms included in this study, with prevalence often reducing by 10% or more (Figure 3). More impressive still was the improvement in hock lesions; all but one farm improved in some cases hock lesions were essentially eliminated on the farm. Some of the variation among farms in how much improvement was achieved was likely due to variation in how well the changes targeted the limiting factors for that farm. Thus we suggest that the benchmarking process be considered iterative, allowing for change followed by re-assessment, followed by new changes, etc. In this way benchmarking can facilitate a continuous cycle of evaluation and improvements, allowing farmers to judge how well new practices meet their management goals.

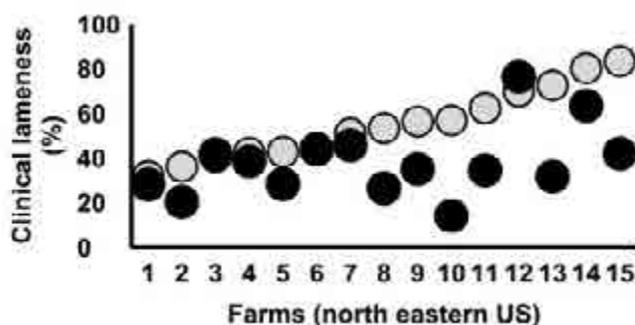

Figure 3. Prevalence (%) of clinical lameness in 15 freestall herds in Northeastern United States in two consecutive farm assessments. Grey and black circles designate the first and second assessment, respectively. Farms are sorted by prevalence at the first assessment (see Chapinal et al., 2014 a).

We believe that that our benchmarking of cow lameness and hock injuries has been successful in getting farmers interested in these

issues, in facilitating the involvement of the herd veterinarian and others into discussions with the farmer on how to address the problems, and at least in some cases leading to real improvements for the cows. In new work we are working to assess these aspects more rigorously, including interviews with farmers and veterinarians, and systematically returning to farms to re-assess outcomes. Our new work is focusing on issues relating to dairy calves, including the perennial issue of failure of passive transfer. We hope to report on our most recent findings during our presentation.

Acknowledgments

The UBC Animal Welfare Program is funded by NSERC's Industrial Research Chair program, with industry contributions from the Dairy Farmers of Canada (Ottawa, ON, Canada), British Columbia Dairy Association (Burnaby, BC Canada), Westgen Endowment Fund (Milner, BC, Canada), Intervet Canada Corporation (Kirkland, QC, Canada), Novus International Inc. Introduction

To feed the growing population – about two billion more people in 2050-animal protein supply has to be increased. The number of animals will not grow at the same rate, but milk and derivatives as also meat will be needed to fulfil the demand. As a consequence more productive cattle is needed and the herds size will increase, predisposing factors for disease spread will be a challenge for Veterinarians.

Objective

The objective of this symposium is to exchange with cattle professionals views on the latest developments with advanced thinkers and doers in cattle science and practice.

Dairy

Global changes in climate, economics, societal pressure, demographics and available resources will have an impact on health management on dairy farms. Fewer farms with a generally less experienced workforce will need to produce more milk for a growing population. These large and growing dairy farms will need to be ready for global climate change causing a change of ecological niche of infectious diseases present on dairies, while societal pressure will result in a reduction of antibiotic use and an increase in concerns on animal welfare. Finally, a reduction in arable land, due to an expanding need for housing and industry, that is available for agriculture will require a greater efficiency of production. Health management of farms will therefore be in continuous transition and veterinary input of these farms will need to adapt to these changes.

Beef

In the case of beef although beef feedlot operations have become more sophisticated in managing health problems, significant economic losses from BRD continue to be related to morbidity and mortality rates, reduced feedlot performance, and metaphylactic and therapeutic regimen costs. The use of simple or complex descriptive epidemiology to study and monitor patterns of disease, as well as data mining and statistical investigations to identify and quantify the impact of potential risk factors, are critical for generating new ideas or hypotheses for potential disease control/mitigation strategies. Subsequently, large-scale clinical trials can be successfully used to evaluate the biologic impact of these strategies on animal health, feedlot performance, and carcass characteristics so that the overall economic impact of each strategy can be determined.

Conclusion

As a consequence of increasing animal protein demand herd size will increase. Diseases in cattle are changing and will be affected by the herd sizes, high production and environmental factors. The latest insights on the influence on cattle health are shared in this symposium.

Abstract

A crucial period in the management of dairy cows may be described from dry off to early lactation. This series of short talks focuses on the reduction in function of the innate immune system that occurs in the weeks surrounding calving and its consequences (Kehrli M.E. 1999). Elanco Animal Health have launched an innovative cytokine, to address this reduction in innate immune function. Bovine granulocyte colony stimulating factor (bGCSF) acts to restore the function and increase the number of neutrophils when administered the week before, and at calving. This unique mode of action has been shown to reduce clinical mastitis in early lactation (Kimura K. 2014). This symposium will address the consequences of immune suppression in both the udder and the uterus and allows the audience an opportunity for discussion. The short talks will be introducing the functions and interactions of the innate immune system at calving, the role of the innate system in the endometrium and an analysis of field data regarding key parameters related to immune function, such as mastitis, retained placenta and metritis.

Sandro Cavirani,

President of the Degree Course in Veterinary Medicine at the University of Parma, ITALY

Claude Hamers,

Senior Veterinary Scientist, Clinical Research & Development

Objectives

Bovine Respiratory Disease (BRD) is a complicated and economically significant pathogen or “germ” challenge for producers, clinicians and the animal health industry as a whole. The solution to better management of it involves a comprehensive herd or population approach, with vaccination programs in young calves (the early bird) a key component. Sounds logical and self-evident but usage of the right antigens at the right time in the right calf vaccination program is not easy to achieve.

Materials & Methods

The symposium will initially briefly cover some of the underlying microbiological, husbandry and anatomical precursors to BRD as well as highlighting why vaccines should be a key pillar of control even though their benefit is sometimes in question. The bulk of the discussion will be around the concepts of herd immunity, pathogen targeting and appropriate vaccination approaches for calves. Pathogen epidemiology, bovine immunology, the role of maternally derived antibodies and vaccinology principles will all be covered in this review. Microbiological and other data from Europe will be used to emphasise a number of the principles. Finally, a new multivalent vaccine (Bovalto) will be briefly presented as an option to consider in vaccination programs for BRD.

Results & Conclusions

It is clear that a high proportion of young calves need to be vaccinated, passive transfer failure needs to be considered in programs and regular reviewing of the pathogen challenge mix is required if an effective herd health approach is to be used. It is also possible that the timetable of vaccination needs to be reconsidered in some circumstances. Finally, it is proposed that it may be time for Buiatrics to consider at least some BRD pathogens as core vaccination targets in both dairy and beef cattle.

MSD programs supporting disease prevention

MSD Animal Health will host a symposium titled The Value of Disease Prevention 'Starts Here' Wednesday, July 6th at 17:00 in auditorium. The symposium will feature presentations by guest speakers from Danone and the Irish veterinary profession. Didier Moreau, Global Director for milk quality at Danone and Frank O'Sullivan cattle practitioner and thought leader in the field of preventive health in cattle will present and discuss how averting disease creates value to dairy product customers and the importance of having a strategic approach to an on-farm prevention program.

The final speaker, Jeroen van de Ven, head of MSD Animal Health's global ruminants business, will explain the role MSD Animal Health plays in helping develop new approaches to disease prevention on farms around the world.

We invite everyone to join us at this symposium to engage in this important subject during a time in our industry when, the way we manage the health of animals, is under increasing scrutiny.

Detection of *Chlamydia* spp and *Chlamydia*-like organisms in placental tissue of bovine abortions in Flanders

Hans Van Loo¹ *Bart Pardon² Marcella Mori³ Daisy Vanrompay⁴ Luc Vanholme⁵ Piet Deprez²

¹DGZ Vlaanderen, Drogen, ²Department of Large Animal Internal Medicine, Faculty of Veterinary Medicine, Ghent University, Ghent, ³Veterinary and Agrochemical Research Centre, Brussels, ⁴Department of Animal Production, Ghent University, Ghent, ⁵Federal Agency for the Safety of the Food Chain, Brussels, Belgium

Objectives: To monitor brucellosis in Belgium, farmers are required to report each ruminant abortion to the Federal Agency for the Safety of the Food Chain (FASFC). Besides brucellosis monitoring, the abortion program concurrently screens the submitted samples for several infectious pathogens. Despite the extensive number of analyses included in this abortion program, about 60% of cases remain undiagnosed. One of the possible explanations could be the presence of unidentified abortifacients like *Chlamydia* spp (CS) and *Chlamydia*-like organisms (CLO). The aim of this study was to evaluate bovine abortions in Flanders for the presence of CS and CLO.

Materials and Methods: Between August and November 2013, placentas of 163 late term aborted and 42 healthy calved control cows were collected and analysed using a *pan-Chlamydia* PCR, a *Chlamydia abortus* PCR and a *Parachlamydia acanthamoebae* PCR. CS positive samples were subsequently reanalysed with a *Chlamydia psittaci* PCR. Histological examination was performed on each placenta sample. All abortion cases were also tested for brucellosis by *Brucella* spp culture on the placenta and serology on maternal serum, for *Neospora caninum* by analysis for antibodies on maternal serum, for bovine viral diarrhoea virus by Ag ELISA on fetal spleen and for *Coxiella burnetii* by PCR on fetal abomasal tissue. The fetus was assessed by aerobic bacteriological culture, *Listeria* spp culture and yeast/fungal culture on abomasal and lung tissue.

Results: None of the samples were positive for *C. abortus*. Ten of 163 (6.13%) abortion placentas were positive for CS of which 3 (1.84%) were identified as *C. psittaci*. Seventy-two (44.17%) abortion placenta samples appeared PCR positive for *P. acanthamoebae*. Of the non-abortion control placentas, 1 of 42 (2.38%) sample tested positive for CS (not identified as *C. psittaci* positive), and 4 (9.52%) samples were *P. acanthamoebae* positive.

In 72 of 163 (44.17%) abortion cases, it was possible to detect a potential infectious abortifacient pathogen, different from CS or CLO. In the 91 non-diagnosed abortions, 6 (6.59%) cases were CS positive while 43 (47.25%) cases were *P. acanthamoebae* positive.

Thirty-nine (23.93%) abortion placenta samples were affected by a purulent (necrotic) placentitis, whereas only 2 (4.76%) non-abortion placenta samples were diagnosed with such a placentitis. Twenty of the 82 (24.39%) CS or CLO positive samples showed to have a purulent (necrotic) placentitis.

Conclusions: The detection of CS and especially CLO in a substantial number of bovine abortions, combined with the indicative histological lesions, suggests a potential role of these pathogens in (un)diagnosed cases of bovine abortion in Flanders. Because of the potential risk for zoonotic transmission of CS and CLO, further research is advisable.

Project financially supported by the FASFC and Sanitary Fund.

Lethal chondrodysplasia in a family of Holstein cattle is due to a *de novo* mutation in the COL2A1 gene

Jørgen S Agerholm¹, *Fiona Menzi² Fintan J. McEvoy³
Vidhya Jagannathan² Cord Drögemüller²

¹Department of Large Animal Sciences, University of Copenhagen, DK-1870 Frederiksberg C, Denmark, ²Institute of Genetics, Vetsuisse Faculty, University of Bern, CH-3001 Bern, Switzerland, ³Department of Veterinary Clinical and Animal Sciences, University of Copenhagen, DK-1870 Frederiksberg C, Denmark

Objectives: Lethal chondrodysplasia is a well-known congenital syndrome in cattle and occurs sporadically in many breeds. A genetic aetiology has been suspected in many cases, but causal mutations have not been identified until recently. However, chondrodysplasia still remains a puzzle, e.g. cases have occurred among the offspring of a French Holstein sire without significant inbreeding. Genomic analysis of those cases revealed that the mosaic sire transmitted a dominant acting missense *COL2A1* mutation. In 2015, the Danish Holstein sire VH Cadiz Captivo produced several cases of chondrodysplastic calves. Here we report the investigation of these cases.

Materials and Methods: Three malformed calves were submitted and examined by necropsy, histopathology, radiology and computed tomography scanning. Tissue was obtained from additional two cases. Breeding data were analysed based on centrally registered calving data and a questionnaire sent to the breeders. To map candidate regions for the chondrodysplastic condition, genomic DNA of four affected calves, their dams and the sire was used for genotyping of 777,962 SNP markers. Subsequently genetic linkage analysis was carried out. For mutation analysis the whole genome of one affected calf was sequenced using next-generation sequencing technology. Finally, the identified candidate mutation was genotyped using genomic DNA of all five cases, their dams, and the sire by direct sequencing of a targeted PCR product using standard Sanger sequencing.

Results: The calves were morphologically similar and displayed severe disproportionate dwarfism ("bulldog" syndrome) and reduced body weight. The syndrome was briefly characterized by shortening and compression of the body due to reduced length of the spine and the long bones of the limbs. The vicerocranium had severe dysplasia and palatoschisis. The bones had small irregular diaphyses and enlarged epiphyses consisting only of chondroid tissue.

Analysis of breeding data showed that 12.4% (64/515) of the offspring of the sire had chondrodysplasia. Genetic analysis revealing significant linkage to several regions of the bovine genome including chromosome 5 where sequencing revealed a point mutation (g.32473300 G>A) affecting the *COL2A1* gene, which represents a striking candidate gene for bovine chondrodysplasia. The *COL2A1* mutation was predicted to affect splicing because it altered the conserved splice donor sequence GT at the 5'-end of intron 36, which was changed to AT. All five cases carried the mutant allele in heterozygous state and all five dams were wild type GG. The sire VH Cadiz Captivo was shown to be a gonadal and somatic mosaic as assessed by the presence of the mutant allele at levels of about 5% in peripheral blood and 15% in semen.

Conclusions: The lesions were consistent with chondrodysplasia. Genomic analyses identified a causative spontaneous dominant acting mutation in *COL2A1*, which must have occurred during the early foetal development of the sire. Germline mosaicism is a relatively frequent mechanism in the origin of genetic disorders and explains the prevalence of a certain fraction of affected offspring. Paternal dominant *de novo* mutations are a risk in cattle breeding, especially because the ratio of defective offspring may be very high and be associated with significant animal welfare problems.

AS-050-003

Are Low Hepatic Mineral Concentrations Contributing To Aborted, Stillborn And Weak Neonatal Calves?

Robert Van Saun^{1,*}

¹Veterinary & Biomedical Sciences, Pennsylvania State University, University Park, United States

Objectives: Fetal abortion and stillbirth are significant pregnancy wastage events contributing to low reproductive efficiency in dairy and beef cattle. Early calf mortalities further contribute to overall reproductive losses. Unfortunately definitive diagnostic outcomes for abortion or stillbirth submissions continue to be less than desired resulting in unknown etiology for more than 30-40% of cases. The study objective was to determine if hepatic trace mineral concentration differences were present among abattoir, aborted, stillborn and neonatal mortality calves in suggesting a potential role for mineral nutrition in perinatal calf losses.

Materials and Methods: Hepatic mineral concentrations (n=382) were retrospectively compared across various populations of fetal and neonatal calves, which died during gestation (n=106), parturition (n=27) or postnatally (n=64; within 2 months of birth) and had been submitted for diagnostic analysis. A population of fetal livers were collected from an abattoir (n=185) were used as "healthy" control comparisons. All liver mineral concentrations were determined by the same university laboratory by inductively coupled plasma spectroscopy (ICP/MS) methods. Mineral concentrations were determined on a wet weight (WW) basis and converted to dry weight (DW) basis using determined liver dry matter content. Measured minerals included calcium (Ca), cobalt (Co), iron (Fe), magnesium (Mg), manganese (Mn), selenium (Se) and zinc (Zn). Abortion and neonatal death submissions were categorized based on laboratory diagnosis as either dystocia (n=35), infectious (n= 36 fetal; 7 stillborn; 40 neonate) or idiopathic (n=35 fetal; 20 stillborn; 24 neonate). Population source (abattoir, abortion, stillborn, neonate), gender, age, breed and other descriptive information were collected. Analysis of variance (ANOVA) models were used to determine main effects of source, disease status, breed (dairy, beef), age (fetal, neonate) and all interactions on hepatic mineral concentration. Orthogonal contrasts were made to evaluate differences in hepatic mineral concentrations based on differing study populations and disease status. Breed was not equally distributed across all populations and was used as a covariate to adjust means.

Results: Across all samples and accounting for breed but not disease status, abattoir samples had greater (P<.0001; .06 for Fe; .003 for Se) concentrations of most minerals, except Ca and Co where they were lower (P<.0001) compared to abortion and stillborn sources. Neonatal samples had lower (P<.054, .018 and .002) Se, Fe and Zn; higher (P<.07, .0001, .0001, and .0001) Ca, Co, Mn and Mo; and were not different in Cu or Mg concentrations compared to abattoir samples, respectively. Breed influenced Se (P<.0001), Ca (P=.04), Cu (P=.002), Fe (P=.03) and Zn (P=.04) with dairy having higher concentrations compared to beef calves for all minerals, except Fe. Disease status influenced (P<.0001) Ca, Cu, Mg, and Co (P=.07), Mo (P=.08) and Zn (P=.01). A source by disease status interaction influenced Cu (P=.0008), Fe (P=.09) and Mn (P=.0065). A source by breed interaction was seen with Ca (P=.0002), Cu (<.0001) and Zn (P=.05). Stillborn calves not caused by dystocia had lower liver Cu (304.0 vs 454.6 µg/g DW; P=.0038), Co (0.066 vs. 0.44 µg/g DW; P<.0001), Mg (500.6 vs. 612.7 µg/g DW; P=.012) and Zn (376.0 vs. 754.1 µg/g DW; P=.0049) compared to those due to dystocia. A number of mineral concentrations, primarily Cu, Ca, Mg, Mn, Zn and Mo in abattoir samples were different from abortion, stillbirths and to a lesser extent neonatal samples. Idiopathic neonatal deaths had lower Mn (6.3 vs. 10.0 µg/g DW) and higher Cu (477.4 vs. 360.4 µg/g DW) and Fe (1102.0 vs. 629.1 µg/g DW) concentrations compared to infectious losses.

Conclusions: Observed differences in hepatic mineral concentrations between abattoir, abortion, stillborn and neonatal mortality calves are suggestive of mineral status being critical to the survival of the fetus during gestation and perinatal period. Trace minerals are involved in a wide range of metabolic functions, including immune function and antioxidant status, which could underpin viability of fetus or calf during the perinatal period. This study's results do not confirm a direct cause and effect, but provide a possible connection that requires further controlled research to confirm the association.

Comments: Research funded by the Pennsylvania Department of Agriculture.

Bovine Leptospirosis, genotyping and serological diagnosis of bovine abortion cases associated with jaundice in the fetus

Laurent Delooz^{1,*}, Guy Czaplicki¹, Fabien Gregoire¹, Fabiana Dal Pozzo², Floriane Pez³, Angeli Kodjo⁴, Claude Saegerman²

¹Santé animale, ARSIA asbl, CINEY, ²UREAR, ULg - FMV, Liège, Belgium, ³BioSellal, ⁴Laboratoire des Leptospores, VetAgro Sup, Lyon, France

Objectives: Leptospirosis is a global disease with potential major economic impact on livestock industries and important zoonotic capacities. The disease surveillance in the developing economies represents a major challenge as humans and animals frequently live in close association such as veterinary and farmers. The serovar Hardjo of *Leptospira* whose primary host is cattle has been studied extensively, but few data exist on other current circulating or emerging serovars. To better understand the disease in cattle and how to prevent and/or control it, it is necessary to identify the genotype and the serovar of circulating *Leptospira*.

Materials and Methods: Between January 2009 to December 2014, 5368 herds submitted to the laboratory 18,014 cases of bovine abortions including at least a foetus. Samples were obtained in the context of the passive surveillance program for brucellosis and were collected by the local veterinary practitioner within 48h after abortion and sent to the regional laboratory of southern Belgium (ARSIA) together with an anamnesis. Sera of the dam were tested using the standardized panel of analyses and were subsequently stored at -20°C. An autopsy and a standardized panel of analyses were performed on organs that were subsequently stored at -20°C. In addition, a *Leptospira interrogans* spp. RT-PCR (ThermoFisher, France), a *Leptospira* genotyping method by multilocus sequence typing (Biosellal, France) and a microscopic agglutination tests (Laboratoire des Leptospores, VetAgro Sup, France) were subsequently performed on some samples.

Results: This study presents results of several investigations performed on a historical Belgian collection of congenital jaundice in bovine aborted fetus cases in order to identify and characterize its *Leptospira* etiology. The serovar and the genotype of two pathogenic *Leptospira* strains were determined, i.e. *Leptospira kirscheneri* Grippotyphosa serogroup and *Leptospira interrogans* Australis serogroup. In addition, microscopic agglutination tests revealed also that serogroups Grippotyphosa and Australis were the most prevalent with respectively 17/42 and 13/42 positive MAT. To identify a specific seroconversion against leptospiral serogroup, a paired serology with an average interval of 60 days between samplings was performed after abortion on twenty dams. Seroconversion was only observed for Australis serovar on three aborted dams.

Conclusions: In conclusion, this study allows the association of two pathogenic *Leptospira* strains to congenital jaundice in bovine aborted fetuses. As a consequence, this clinical sign should be considered as an additional clinical picture of bovine leptospirosis. Considering the difficulty to diagnose this disease among infected cattle, the diagnostic approach established by ARSIA seems to be an efficient method under field conditions in which the veterinary practitioner performs samples in cattle farms.

AS-050-005

An outbreak of congenital chondrodystrophy of unknown origin (CCUO) among commercial beef calves in central Alberta

Elizabeth R. Homerosky¹, *Carolyn H. Legge² Edouard Timsit¹ P. Tim Guichon³ Eugene D. Janzen¹

¹Department of Production Animal Health, ²Department of Ecosystem and Public Health, University of Calgary Faculty of Veterinary Medicine, Calgary, ³Guichon Veterinary Services Inc., Okotoks, Canada

Objectives: An outbreak of congenital joint laxity in the presence or absence of chondrodystrophy occurred at a commercial cow-calf operation in central Alberta during spring of 2014. All affected calves were born to home-raised crossbred heifers and sired by a single Angus bull. There was no history of feeding silage, which has previously been associated with outbreaks in Canada. The objective was to investigate other etiologies of congenital chondrodystrophy.

Materials and Methods: During mid-November 2013 bred heifers were moved from summer grazing pasture to winter pasture with well-sourced water. The producer reported feeding approximately 16.8kg of grass hay (chopped round bales) and 1.4kg of barley per head per day. They were supplemented with varying brands of commercial trace mineral and salt with added selenium (approximately 20kg every 1.5 to 2 weeks.) The mature cow herd was pastured separately and received the same source hay and mineral but no barley. The winter was notably harsher than usual with increased snowfall and below average temperatures.

Heifers began calving March 11 extending to May 15, 2014. During that time 29 of 32 calves born were affected with congenital joint laxity in the presence or absence of chondrodystrophy. There were no apparent trends in calving dates versus severity of abnormalities. However, it is noteworthy that 1 of the 3 normal appearing calves was born to a heifer mistakenly overwintered with the mature cow herd. Cows began calving on March 15 extending to May 21, 2014 and gave birth to all normal appearing calves.

The majority of heifers were assisted in delivery and 5 calves were stillborn. Multiple calves died or were euthanized as a result of complications related to failure to ambulate or thrive after several days of supportive care. Joint laxity resolved in surviving calves by 2 weeks of age. Thirteen of 32 calves born to heifer dams survived until weaning. Residual abnormalities in affected calves included chondrodystrophy, superior brachygnathia, and multiple angular limb deformities.

Results: Five affected calves were necropsied by a board certified pathologist and chondrodystrophy was confirmed in 4 by metacarpal length/diameter ratio. Other than obvious congenital abnormalities, physical examinations of both live and dead affected calves were unremarkable. All heifer dams were normal appearing moderate-framed crossbred heifers with body condition scores at calving ranging between 4 and 5 on a 9-point scale.

The sole sire, along with 4 heifer dams giving birth to affected calves and 2 affected calves were tested for genetic abnormalities. All animals tested negative for carrier status of arthrogyposis multiplex, contractural arachnodactyly, and osteopetrosis. Serum mineral concentration was also analyzed in the 4 heifer dams. Minerals outside of normal range included: high normal molybdenum (3 head), marginal magnesium (2 head), marginal copper (1 head), and deficient copper (1 head). Unfortunately feed was no longer available to be tested for nutrient composition, mold or toxins.

Conclusions: In agreement with several previously reported outbreaks of congenital chondrodystrophy of unknown origin worldwide, this outbreak was associated with spring calving heifers. Genetic causes have been deemed unlikely and a nutritional-related issue, particularly trace mineral deficiency is highly suspected. Lack of feed analyses and imprecise records precluded accurate calculation of estimated daily intakes for minerals critical for normal epiphyseal growth plate formation such as manganese. In addition, the high-risk period (3-6mo. gestation) overlapped with summer grazing and winter pasture time frames further complicating investigation.

AR-037-001

What do UK vets' think about the efficacy of teat sealants versus antibiotics for preventing infections? How does new evidence alter their beliefs?

Helen M. Higgins^{1,*}, Jon Mouncey², Ian Nanjiani², Alex J. Cook³¹School of Veterinary Sciences, University of Liverpool, Leahurst Campus, ²Westpoint Veterinary Group, Dawes Farm, West Sussex,³Veterinary Epidemiology and Public Health, University of Surrey, Guildford, United Kingdom

Objectives: The existing evidence suggests that in uninfected quarters at dry-off, using a teat sealant (TS) instead of an antibiotic (AB) is as effective at preventing new intra-mammary infections (IMI). Changing from an AB to a TS can considerably reduce antibiotic use. The aims were:-

1. To quantify vets' current beliefs regarding the efficacy of an AB versus a TS at preventing new IMI in uninfected quarters at dry-off.
2. To quantify how vets' update their clinical beliefs when presented with new data that challenges their current beliefs.
3. To assess how logically vets alter their beliefs in the light of new evidence.

Materials and Methods: In total, 20 face-to-face interviews were conducted with UK farm vets located in six practices in the South of England. Probabilistic elicitation (roulette method) was used to capture the vets' current beliefs as probability distributions (called the "prior distributions"). Thereafter, the vets were shown new data that challenged their current beliefs. The vets' beliefs were re-captured as probability distributions in light of the new information (called the "posterior distributions"). We assessed how logically the vets' updated their beliefs by comparing how they changed to a gold standard - predictions from Bayes theorem.

Results: For 17 vets, the mode of their prior distribution (i.e. their "best guess") indicated that a TS was superior to an AB at preventing new IMI. However, there was clinical ambiguity, such that 12 out of the 20 vets assigned some probability that the AB was the superior treatment, with the remaining 8 vets giving negligible probability to this event. There was also heterogeneity in the magnitude of the difference in the treatment efficacy expected between the two treatments.

In total, 4 out of the 20 vets updated their beliefs perfectly logically in light of the new data (both central location and variance). Furthermore, the majority (18/20) centred their posterior distributions correctly. However, the majority (16/20) did not adjust the variance of their posterior distributions in keeping with Bayesian predictions. Specifically: 8 vets had posterior distributions with variance less than their prior but greater than predicted, 6 had posterior distributions with variances equal to their prior, and 2 had posterior distributions with variances greater than their prior. Thus, many vets did not draw as much confidence from the new data as could logically be expected.

Conclusions: Results suggest that some vets are not entirely convinced of the efficacy of teat sealants. This has important implications for responsible antimicrobial prescribing, especially given there are many potential challenges with changing from AB to a TS.

Evidence-based practice relies heavily on changing beliefs by presenting new data. Yet people do not always respond logically when shown new data, especially if it contradicts their pre-existing beliefs. Our results suggest that some vets may benefit from additional training to help them update their beliefs appropriately and to facilitate the efficient transfer of new evidence into practice.

AR-037-002

Developing a multifaceted, collaborative, practice-wide approach to responsible medicines use on farms

David A. Tisdall¹, *David C. Barrett¹, Kristen K. Reyher¹¹School of Veterinary Sciences, University of Bristol, Bristol, United Kingdom

Objectives: Langford Farm Animal Practice (LFAP), a clinical teaching practice of the University of Bristol, has a long history and developed culture of proactively engaging with farm clients to encourage responsible antimicrobial use. The objective of this ongoing project is to demonstrate that farm animal veterinary surgeons in a commercial practice, working in partnership with farmers, can minimise the risk of antimicrobial resistance (AMR) development without compromising animal health and welfare, by reducing total and critically important antimicrobial use on farm through improved herd health management (HHM) and systematic medicines auditing.

Materials and Methods: LFAP serves 220 farms in Somerset, UK, representing approximately 1500 dairy cows with an average herd size of 150; 3300 beef cattle and a similar number of sheep, with smaller numbers of other species. A multifaceted, practice-wide, collaborative approach combining changes to HHM and prescribing policy with systematic medicines audits and farmer training was adopted. Farmers' meetings and newsletter articles raised awareness, encouraged engagement and provided training on compliance and responsible use.

Beginning in 2009, fluoroquinolone use was halted and critically important antimicrobials progressively withdrawn from first-line treatments. Fourth-generation cephalosporins were removed, and third-generation cephalosporins replaced with first-generation cephalosporins or aminopenicillins. Calf pneumonia cases were treated with oxytetracycline or florfenicol, as an alternative to longer-acting macrolides.

Farm- and practice-level medicines audits were introduced in 2012 as part of HHM and clinical governance, respectively, using a bespoke Excel (Microsoft Office 2010) spreadsheet. An annual retrospective analysis of medicines use data at practice level from 2010 onwards was completed. Multiple measures were used for benchmarking, including animal daily doses at farm level and total milligrams per year at practice level, due to the broad species demographic. Consideration of both animal health and economic implications of current medicines use, including the balance between preventive interventions and reactive treatments, allowed targeted recommendations to be made.

Results: Unless otherwise stated, at practice level, total milligrams of antimicrobials used is reported.

No fluoroquinolones have been prescribed since 2009. Respectively, 89.8% and 63.5% reductions in the systemic use of third/fourth-generation cephalosporins and macrolides were achieved. Macrolides now account for less than 0.1% of antimicrobial treatments for pneumonia. Intra-mammary use of fourth-generation cephalosporins in the treatment of mastitis was reduced by 99.7%. These now account for 0.2% of lactating cow intra-mammary tubes, compared to 32.7% in 2010.

Overall this equates to an 87.3% reduction in the use of fluoroquinolones, third/fourth generation cephalosporins and long-acting macrolides, compared to 2010 levels. Total antimicrobial use in milligrams increased by 5% over the same period, against a 10% increase in dairy cattle numbers and an overall reduction in the number of courses prescribed. There was no evidence of declining herd health or cure rates (whether real or farmer-perceived) with a move to first-line treatments.

Farm clients have been consistently positive about tackling the issues of responsible medicines use and AMR in partnership with the practice. Concern over farmer willingness to participate was unfounded. Informal

feedback suggests farmers have found measures which express antimicrobial use in terms of doses, courses or economics most useful.

Conclusions: Medicines audits are a useful and effective tool to both monitor and drive responsible antimicrobial use and to reduce total antimicrobial use in food-producing animals. It is likely that the combination of a collaborative approach, which built upon the existing, relationship of trust between farmers and veterinary surgeons, with a focus on improved HHM, contributed to success. For practitioners interested in responding to the threat of AMR, this work demonstrates that marked reductions in the use of critically important antimicrobials can be achieved, whilst keeping farmers engaged and continuing to improve animal health and welfare.

AR-037-003

Antimicrobial resistance in large Swedish dairy herds with high or low calf mortality risk

Maria Torsein^{1,2},*Ann Lindberg³Charlotte Hallén-Sandgren⁴Ulrika Grönlund⁵Catarina Svensson⁶Charlotte Berg²

¹Farm and Animal Health, ²Department of Animal Environment and Health, Swedish University of Agricultural Sciences, Skara, ³Department of Disease Control and Epidemiology, National Veterinary Institute, Uppsala, ⁴DeLaval International AB, Tumba, ⁵Anicura, Stockholm, ⁶Department of Clinical Sciences, Swedish University of Agricultural Sciences, Uppsala, Sweden

Objectives: Calf mortality is reported worldwide as an important cause of economic loss in dairy production. Previous studies have shown that a high calf mortality was associated with higher antimicrobial use. Commensal *Escherichia coli* can acquire resistance genes or develop resistant mutants; these are regarded as indicators of the antimicrobial exposure of their host. In this study we aimed to evaluate if treatment and management regimes at herd level were associated with antibiotic resistance in *E. coli* at individual level and also to evaluate if risk factors for resistance were associated with type of herd (high versus low calf mortality risk).

Materials and Methods: Sixty large dairy herds were enrolled in the study. All were affiliated to the Swedish official milk recording scheme, which covers 90% of all Swedish dairy cows and involves detailed recording of data on management and production. The inclusion criteria were: herd size ≥ 160 cows, calf mortality risk (day 1-90) $\geq 6\%$ (HM-high mortality) or $< 2\%$ (LM -low mortality). The herds were visited once during December 2005 to March 2006 and up to 5 faecal samples were collected per rectum from visually healthy calves 1-14 days of age. Samples from calves which had been treated with antimicrobials were omitted in the statistical analyses. All faecal samples (n=238) were streaked onto MacConkey agar plates. Antimicrobial susceptibility testing was carried out for lactose-positive isolates using cut-off values set by the European Committee on Antimicrobial Susceptibility Testing.

Treatment and management variables (n=21) were first screened using univariable logistic regression with either antimicrobial resistance (at sample level) as outcome or type of herd (HM/LM; at herd-level). Variables associated with type of herd at $p \leq 0.20$ were qualified for further multivariable analysis. In total, six multivariable models with resistance to different types of substances as outcome were evaluated: resistance to nalidixic acid, sulfamethoxazole, streptomycin, tetracycline, ampicillin and presence (0/1) of multiresistance to ≥ 5 substances.

Results: None of the calves in the analysis had received antimicrobial

treatment. The five substances for which resistance was most frequently shown, were nalidixic acid, sulfamethoxazole, streptomycin, tetracycline and ampicillin corresponding to 65%; 55%; 46%; 42% and 40% resistance. Presence of resistance against these substances were ranked in the same order in HM and LM herds. All herds, except one, showed antimicrobial resistance to at least one substance. Of the 226 samples, 44 samples (24%) were diarrhoeic (nHM=29; nLM=15). Diarrhoeic samples were significantly more common in high mortality herds ($p=0.012$; OR: 2.4; 95% CI: 1.21–4.80).

Multivariable analyses: The model with nalidixic acid as outcome remained non-significant. All models with resistance as outcome had one thing in common: a diarrhoeic sample was significantly associated with higher odds of resistance. The model with sulfamethoxazole as outcome showed higher odds for resistance for herds starting antimicrobial treatment against pneumonia earlier; when calves were coughing compared starting treatment when calves had fever ($p=0.007$; OR: 10.13; 95% CI:1.86-55.14). Associations with type of herds were demonstrated in the model with multiresistance to ≥ 5 substances, with more multiresistance in HM herds (OR: 2.28; 95% CI:1.15-4.52). Multivariable results from all of the models will be presented.

Conclusions: Antimicrobial resistant bacteria were common in calf faecal samples with loose consistency (diarrhoeic samples). Herds with high calf mortality had higher prevalence of multi-resistance to ≥ 5 substances. Because none of the sampled calves had been treated with antibiotics this indicates other routes of introduction of antimicrobial resistance than treatment of the calves. An excessive use of antimicrobials for early treatment of pneumonia is associated with higher odds for sulfamethoxazole resistance.

AR-037-004

MRSA in organic dairy farms in Germany – is it an issue?

Bernd-Alois Tenhagen¹,*Alexandra Fetsch¹Mirjam Grobbel¹Katja Alt¹Annemarie Käsbohrer¹

¹Biological Safety, Federal Institute for Risk Assessment, Berlin, Germany

Objectives: Antimicrobial resistance (AMR) is currently one of the major public health issues. Public perception relates AMR rather to conventional than organic farming. The objective of this study was to compare the prevalence of methicillin-resistant *Staphylococcus aureus* between bulk tank milk (BTM) from organic and conventional dairy farms in Germany.

Materials and Methods: Sampling was carried out in 2014 and distributed across the country based on the regional distribution of conventional and organic dairy cows in Germany. BTM samples (25 ml) were analysed by regional laboratories for MRSA using a double selective enrichment method. Isolates were sent to the National Reference Laboratory for coagulase-positive *Staphylococci* incl. *Staphylococcus aureus* (NRL) for PCR confirmation and typing. Resistance to 19 antimicrobials was tested using the broth microdilution method according to CLSI standards by the National reference laboratory for antimicrobial resistance. Minimum inhibitory concentrations were evaluated according to EUCAST epidemiological cut off values.

Results: Overall, 9.7 and 1.7 % of 372 and 303 analysed samples from conventional and organic dairy farms respectively tested MRSA-positive. From conventional dairy farms, 36 isolates were sent to the NRL for

typing and resistance testing. Five isolates originated from organic farms. Most isolates (34 and 4) had spa-types related to the clonal complex CC398. However, 1 organic and 2 conventional isolates had spa-types related to other clonal complexes, one of those being a typical human associated type (spa-type t790, CC22). Overall MRSA from conventional dairy farms were only slightly more resistant than those from organic farms. However, as only few MRSA were submitted from organic farms no statistical evaluation was valid.

Conclusions: Results indicate that MRSA are less prevalent in organic than in conventional dairy herds in Germany. Compared to similar studies 2009 (4.1 %) and 2010 (4.7 %) the proportion of MRSA positive conventional dairy herds increased substantially. Moreover, non-CC 398 Isolates had not been detected in that study. As *S. aureus* is an important mastitis pathogen in cattle, spread of MRSA is worrisome not only from a public health perspective. Although significantly less frequently organic dairy herds also harbour MRSA.

Comments: The authors are grateful to the regional laboratories performing the primary isolation and to the Federal Office for Consumer Protection for support in data collection.

AR-037-005

Antimicrobial resistance in *E. coli* from organic and conventional dairy herds in Germany

Bernd-Alois Tenhagen ^{1,*}, Mirjam Grobbel ¹, Beatriz Guerra ¹, Katja Alt ¹, Annemarie Käsbohrer ¹

¹Biological Safety, Federal Institute for Risk Assessment, Berlin, Germany

Objectives: Antimicrobial resistance (AMR) is currently one of the major public health issues. Public perception relates AMR rather to conventional than organic farming. It was the purpose of this study to compare AMR in *E. coli* harvested from bulk tank milk (BTM) in conventional and organic dairy herds in Germany

Materials and Methods: Sampling was carried out in 2014 and distributed across the country based on the regional distribution of conventional and organic dairy cows in Germany. BTM samples (25 ml) were analysed by regional laboratories for *E. coli* and isolates were sent to the National Reference Laboratory for Antimicrobial Resistance at the BfR. Resistance to 14 antimicrobials was tested using the broth microdilution method according to methods described in Commission Decision 2013/652/EC on the harmonized monitoring of AMR in the food chain in the EC. Minimum inhibitory concentrations were evaluated according to EUCAST epidemiological cut off values.

Results: Regional laboratories sent 74 and 122 isolates of *E. coli* from organic and conventional dairy farms respectively. The vast majority of the isolates was susceptible to all 14 test substances. Of the 3 organic isolates (4.1 %) that were resistant to at least one substance, all were resistant to tetracycline, one additionally to ampicillin and another one to tetracycline and sulfamethoxazole. Among the 13 conventional resistant isolates (10.7 %) resistance to ampicillin (7 isolates), sulfamethoxazole (7) and tetracycline (6) was also most prevalent. However, resistance to ciprofloxacin, a fluoroquinolone (2), colistin (1) and ceftazidime, a 3rd generation cephalosporin, (1) were also observed.

Conclusions: Results underline that overall, AMR is not a major issue in dairy herds. However, the proportion of resistant *E. coli* was even lower in organic dairy herds and resistance was only observed to comparatively old antimicrobials with widespread resistance in other

food animal populations. In contrast, isolates from conventional farms showed some diversity in resistance which might reflect differences in selective pressure in the herds.

Comments: The authors are grateful to the regional labs for doing the primary isolation.

AR-037-006

Antimicrobial Use In Dairy Cattle In New Zealand: A National And Regional Benchmarking Study

Mark Bryan ^{1,*}, Shen-Yan Hea ², Elena Knupfer ³

¹Head of R&D, ²Epidemiologist, VetSouth Ltd, Southland, ³VetSouth Ltd, Winton, New Zealand

Objectives: The New Zealand Veterinary Association (NZVA) has recently set an aspirational goal of using zero antimicrobials for the maintenance of animal health and welfare by 2030. A key strategy in achieving this goal is understanding the current use rates of antimicrobials.

The objective of this study was to measure and understand antimicrobial use and trends in New Zealand dairy cows, and to set a baseline level to facilitate benchmarking and the monitoring of antimicrobial use at a national level. Two databases were utilised, representing cows in Southland only, and a national database representing cows in all regions of New Zealand.

Materials and Methods: Southern regional antimicrobial sales data from dairy clients were extracted from the VetSouth veterinary clinic database (representing approximately 44% of all dairy cows in Southland) for 2013, 2014 and 2015 seasons. In addition, national antimicrobial sales data (2015) was obtained from the WelFarm database (data gathered by 6 participating XLVets veterinary clinics located throughout New Zealand).

The mass of antimicrobial agents sold was calculated by multiplying the volume of product sold by the concentration of each active agent (after accounting for the sales unit). Each active agent was classified by antibiotic class and product type.

The animal biomass (at peak milk, December) was calculated by the multiplication of cow (heifer) numbers by the industry accepted average New Zealand dairy cow (heifer) weight of 460kg (270kg), respectively. If heifer numbers were unavailable for a particular farm, heifer counts were estimated by multiplying the cow number by an estimated average replacement rate of 24%.

Antibiotic sales volume was normalised by dividing the mass of the active ingredients (mg) by the biomass/population correction unit (kg).

Results: A total of 979kg, 1138kg and 1249kg of antimicrobial agents were sold to Southland dairy farmers for 2013, 2014 and 2015, respectively. The total number of cows (heifers) in the dataset were 253,106 (61,652), 259,704 (65,010), and 286,208 (69,293) from 399, 406, 436 farms, for 2013, 2014 and 2015, respectively.

A total of 271kg of antimicrobial agents were sold to 109 dairy clients from 6 regions participating in the WelFarm programme during the 2015 season. The total number of cows (heifers) was 68,337 (16,587), respectively.

Penicillins were the most commonly sold antibiotic by volume (78.0%, 74.4%), followed by macrolides (10.2%, 10.9%), cephalosporins (4.7%, 8.3%) and tetracyclines (4.2%, 4.7%), for VetSouth and WelFarm clients, respectively.

Total annual mg/PCU was 8.31 and 7.57 respectively. The standardised measure of antibiotic use (mg/PCU) for the 2015 season was; aminoglycoside (0.09, 0.09), cephalosporin (0.39, 0.63), quinolone (0.003, 0.003), lincosamide and macrolide (0.85, 0.84), penicillin (6.48, 5.63), sulphonamides and trimethoprim (0.15, 0.02), and tetracycline (0.35, 0.36), for VetSouth and WelFarm clients respectively.

Amongst VetSouth clients, there was a decreasing trend of cephalosporin and macrolide sales (mg/PCU) from 2013 to 2015 (0.71, 0.61, 0.39 and 1.03, 0.90, 0.85, respectively), however there was an increasing trend in penicillin sales (5.01, 6.16, 6.48, respectively).

The most common product type sold (by volume) was injectable products (49.8%, 56.4%), followed by intramammary dry cow (41.6%, 35.1%) for VetSouth and WelFarm clients, respectively.

Conclusions: The data presented sets a baseline level of antimicrobial use in New Zealand. The results show that penicillins are the most commonly used antibiotic in New Zealand dairy cows. Furthermore there appears to be an increasing trend of penicillin use over the last 3 years, whereas cephalosporin and macrolide use has decreased.

These data can also be compared with national –level pan- species antibiotic use data. Data collated from antibiotic sales data has demonstrated an overall annual use rate of between 7.62 and 11.46 mg/PCU for all species. These data demonstrate that dairy cattle fall within the lower- mid range of the overall species data.

AR-037-007

From Policy-Takers To Policy-Makers: Development Of An Antimicrobial Stewardship Policy By Dairy Farmers

Kristen K. Reyher ^{1,*}, Lisa van Dijk ¹, Alastair Hayton ², David Main ¹, David C. Barrett ¹, Henry Buller ³

¹University of Bristol, Langford, ²Synergy Farm Health, Evershot, ³University of Exeter, Exeter, United Kingdom

Objectives: Pressures for more responsible use of antimicrobial medicines in food animals are likely to increase from consumer groups, policy-makers and the food industry, including retailers. Participatory approaches to disease prevention and medicine management offer an innovative way to approach these challenges while maintaining or improving dairy herd health and welfare. This research sought to examine the processes involved in engaging and enabling groups of dairy farmers in the conception, design and implementation of an antimicrobial stewardship policy for a major retailer in the United Kingdom.

Materials and Methods: In this project, dairy farmers, cooperative leaders, veterinary surgeons, researchers and facilitators worked together to conceive of and develop an antimicrobial stewardship policy that would meet the needs of the retailer and would be fully enactable on farms, allowing farmers to reduce and rationalise antimicrobial use without compromising animal health and welfare. All farms (n=80) supplying the retailer were invited to participate, along with their veterinarians, in policy-creating meetings led by a facilitator. The process provided a unique opportunity for collaboration and dialogue between farmers, veterinarians, industry and researchers, with farmers taking a leading role in generating feedback and ideas. Information was sought on farmer and veterinarian attitudes towards antimicrobial resistance and antimicrobial use on their farms. Meetings were loosely structured around a conceptual model (Speksnijder et al., 2015), and specifically addressed disease reduction strategies, ensuring correct use of

antimicrobials, avoiding prophylactic use of antimicrobials and ensuring quality data recording and use. Each of these areas was expanded, and farmer's comments were compiled to develop a framework for a policy which was further refined and finalised following farmer feedback. Implementation of the policy is currently on-going and includes measures agreed by all participating farmers.

Results: Attendance at all meetings was exceptional, with over 95% of farms represented. Veterinary response was also high, with engagement of almost all the veterinary practices servicing the supplier farms. Farmers were responsive and aware of the problem of antimicrobial resistance. Farmers reported enjoying the meetings and felt their voices were heard, however, they also expressed that development of such a policy was difficult and mentally taxing. Veterinarians participated extensively and were also active in discussions. After these initial data-gathering meetings, drafting and refinement of the policy was accomplished by a smaller group of industry representatives, farmer representatives and researchers. Further feedback and refinement of the initial policy was then achieved through follow-up meetings with a larger group of farmer representatives. The agreed policy included aims and measures to achieve more responsible use of antimicrobials, and was accepted by all farmers. Once finalised, the policy was reported to all farmers, and implementation begun. Collaboration of the researchers with the supply chain is ongoing to ensure full compliance and continue adapting the stewardship policy as needed.

The participatory nature of this work encouraged comprehensive learning for all involved. This integration of science with farmers' knowledge and experience led to credible and practical recommendations designed to deliver real and lasting change in antimicrobial use.

Conclusions: The multidisciplinary nature of this research contributed to the embedding of social science skills and approaches into the veterinary sphere. As an initial step in creating better understanding of how participatory approaches with farmers can be applied in a UK context and more widely, this work serves as a pilot for promoting more responsible use of veterinary medicines in other livestock species. Feedback was overwhelmingly positive, and engagement of farmers with the process is expected to lead to increased uptake of changes and improved stewardship of antimicrobials.

BH-019-001

An Epidemiological Study Of A Pneumonia Outbreak In An Irish Beef Feedlot

Damien Barrett ^{1,*}, Ronan O'Neill ², Jennifer McClure ³

¹Sligo RVL, Dept of Agriculture, Food and the Marine, Sligo, ²Dept of Agriculture, Food and the Marine, Dublin, ³Irish Cattle Breeding Federation, Cork, Ireland

Objectives: Pneumonia is the most significant animal health issue affecting the beef industry worldwide. While there is quite an amount of international literature on factors predisposing to pneumonia, there are few recent studies on factors predisposing to pneumonia in Irish beef herds. The objective of this study was to study risk factors associated with the occurrence of pneumonia in an Irish beef herd.

Materials and Methods: The study population comprised of a subset of bulls purchased into an Irish feedlot in 2014.

For each animal purchased, data assembled from the Animal Identity and Movement (AIM) database included their ear tag, the herd of origin, age at purchase, age at death, days on the farm, breed, date of purchase, week of purchase, month of purchase, the mart if any through which they were purchased, the date of slaughter. The following data were assembled from the Irish Cattle Breeding Federation (ICBF) database; weight at purchase, carcass weight and grade at slaughter. The farmer provided the pneumonia treatment status. Descriptive statistics were calculated for the dataset, and univariate and multivariate analysis was carried out.

Results: It was found that the odds of pneumonia occurring in November purchased cattle was twice that of cattle purchased in October, which in turn was twice the odds of pneumonia in September purchased animals. Bulls purchased at a younger age were found to have a greater risk of pneumonia. The odds of pneumonia doubled for each 50 day decrease in age. The live weight at slaughter of non affected bulls was on average 13kg heavier than bulls affected by pneumonia. There was no difference in odds between the 15 marts in which the bulls were purchased, or among the 9 breeds of cattle purchased. Younger bulls purchased later in the year had the greatest risk of pneumonia. The performance of animals affected by pneumonia was significantly diminished.

Conclusions: In addition to the costs of treatment and increased labour, pneumonia reduces the performance of beef bulls. In this study the lifetime performance of affected bulls was reduced by 0.1 kg per day. This loss in performance coupled with the costs of treatment and increased labour are a significant loss to bull beef finishers, and emphasises the need for the control of respiratory disease in feedlots. As part of the control strategy, bull beef finishers should consider purchasing older calves earlier in the season.

BH-019-002

Characterization of bioaerosols in beef cow-calf operations over a 6 month period: relations with environmental risk factors and respiratory disease

Nicolas Herman^{1,*}, Didier Raboisson¹, Jean-Luc Guerin², Gilles Meyer¹

¹Ruminant section, Department of Livestock and Products – Veterinary Public Health, ²INP-ENVT College of Veterinary Medicine of Toulouse - France, Toulouse, France

Objectives: Bovine Respiratory Disease (BRD) is an important economic problem in cattle industry, and is the most common cause of death for pre-weaning beef calves more than 3 weeks old. BRD is due to complex interactions between pathogens and environmental management factors and traditionally associated with poor ventilated housing conditions. Surprisingly, only few data are available concerning the impact of microbial quality of the air on BRD. The objectives of this study were to analyze relationship between air quality, a variety of environmental risk factors and respiratory health in beef cow-calf operations.

Materials and Methods: A Coriolis air sampling device (Bertin technologies) was used to collect samples in 17 beef cow-calf operations buildings, 9 tie stall and 8 free stall barns, each month over a 6 months period (From December to May). Sampling consisted of 10 minutes aspiration at 250L/min in three different barn areas: calf pen, central alleys (tie stall barns) and/or cow straw bedding (free stall barns). Aerosols were collected in 15 mL PBS tween 0.05%, by high-speed cyclonic motion without filtration. Airborne total bacterial counts (cfu/m³) were determined by direct isolation on Trypticase Soy Agar plates (TSA). Airborne total molds counts (cfu/m³) were obtained after isolation on Sabouraud Gentamicin Chloramphenicol 2 agar plates (SGC2). DNA loads of bacteria, Aspergillus and archeal bacteria were quantified by real-time quantitative PCR assays on a LightCycler 480 (Roche). Dimensions of the barn, sidewalls, alleys, calf pens were measured. Calf pens were assigned a box factor (1 to 3) related to the number of solid planes around the calf. During aerosol sampling, temperature, hygrometry and wind speed were recorded using a KIMO HD200 STD data logger (Kimo). Stocking density (m³/kg) was calculated (for each month and each barn) by dividing the barn volume by the product of total number of calves and their average estimated weight. Prevalence of BRD was determined as the percentage of total number of calves treated for respiratory signs at least one time. Statistical analysis was performed thanks to time series mixed linear or binomial regressions with operation as random effect.

Results: Results show large differences of bacterial and mold counts between farms, ranging from 1.2.10² to 6.8.10⁵ cfu/m³ and 1.2 to 2.3.10⁶ cfu/m³ respectively. A large variability between farms was also observed for DNA loads of bacteria, molds and archeal bacteria in aerosols. DNA loads of bacteria and archeal bacteria were correlated (p<0.001) but surprisingly there was only weak correlation between isolation counts and qPCR. No difference in counts was observed between tie stall and free-stall barns (p>0.05) although temperature within barns was significantly higher in tie stall compared to free-stall barns (p<0.001). Within each barn, airborne content was not dependent on the location of sampling. Despite variation in environmental factors, no significant differences were seen within each barn in microbial air content when animals were present (From December to April). Significant difference was tough observed when cattle were in barns or outside (May). A prevalence of BRD of more than 15 % was associated with increasing boxfactor (OR: 2.8, 95 CI=1.1-7.6), decreasing stocking density, and with use of vaccine (P<0.01).

Conclusions: Development of portable air sampling devices has made it clinically feasible to evaluate air hygiene in livestock buildings. Results suggest a large variability in microbial air content between herds, which is not correlated to tie or free stall systems. Within one farm the microbial air content seemed to remain constant until the animals go outside. Prevalence of BRD is correlated to environmental factors and management practice and could be linked to microbial air content. Further studies on quality of the aerosols (NGS and 16S sequencing of air contents) are in progress to determine its impact on BRD.

BH-019-003

The value of using enhanced case definitions for the management of BRD in commercial feedlots

James Lowe ^{1,*}, Wade Taylor ², Tom Noffsinger ², Brian Aldridge ¹, Garrett Taylor ³, Kurt Brattain ³

¹Department of Veterinary Clinical Medicine, University of Illinois, Urbana, ²Production Animal Consultation LLC, Oakley, KS, ³Geissler Corp., LLC, Minneapolis, MN, United States

Objectives: Bovine respiratory disease (BRD) is the primary cause of morbidity and mortality in cattle during the feeding period. Management of BRD cases relies on the observation of cattle behavioral changes by caregivers. Applying multiple ante-mortem diagnostic technologies in combination improves outcomes in the clinical management of BRD.

Materials and Methods: After being identified as sick and pulled from the home pen, cattle are typically moved to a treatment area, where a case definition (CD) for BRD presence, severity and chronicity is assigned by a trained caregiver, based on rectal temperature (RT), attitude and appearance. We applied a computer-based algorithm (Whisper®, Geissler Corp.) to sounds recorded during the initial assessment for suspected BRD of 17,848 cattle from 13 sites to determine if algorithm-based analysis of lung auscultation would improve BRD CD precision. A discrete score (LS) of 1 to 5 was applied to each calf (1 = normal, 5 = chronic or severe BRD) for use in the treatment decision protocol. RT was also a factor in the treatment protocol. Outcomes were measured by case fatalities (CF). We expected a high LS to be associated with a greater chance of CF. A logistic regression model using BW, RT and LS was constructed to estimate the likelihood of CF.

Results: For each 1 unit rise in LS, the likelihood of CF increased by 49.4% adjusted for RT and BW (odds ratio (OR) = 1.494, 95% CI 1.428-1.564). For each 1 degree F increase in RT, the likelihood of CF increased by 19.1% (OR = 1.191, 95% CI 1.149-1.234). There were no interactions between temperature and LS detected. Treatment (antibiotic) was not associated with different outcomes and there was no interactions between treatment and LS or temperature and therefore was not included in the final model.

Conclusions: These data suggest that algorithm-based analysis of lung auscultation is an effective tool in practical applications to predict individual clinical outcomes. Standard case definitions for BRD based on lung auscultation and rectal temperature can improve evaluation of treatment success and can be used in the development of evidence-based treatments for BRD.

BH-019-004

Effects of castration and castration method on growth, morbidity and mortality in bulls 30-50 days post entry to a feed yard

James Lowe ^{1,*}, Kiley Mettendorf ², Jose Valles ³, Kip Lukasiewicz ³

¹Veterinary Clinical Medicine, University of Illinois, Urbana, IL, ²College Of Veterinary Medicine, University of Illinois, Urbana, ³Production Animal Consultation, Oakley, KS, United States

Objectives: Castration is a common practice in feedlot management to reduce the effects of testosterone. The two most common castration methods are surgical castration and banding. This study was conducted

to evaluate the effects of different castration methods between the treatment groups; steers (control), banding with intra-testicular lidocaine (CB), or surgical castration with intra-testicular lidocaine (CS).

Materials and Methods: A total of 144 animals were enrolled in the study. Cattle were blocked by weight at processing. There were twelve blocks in each replicate (pen). All participating animals were enrolled in the trial 40 days post-arrival to the feedyard. Individual animal data collected included: ID tag, weight at enrollment, weight at re-implant, weight 7 days pre-harvest, morbidity, mortality, and the number of cattle approaching the bunk during the first daily feeding for three days following enrollment. All statistical analyses were performed using R program. Collected data was evaluated using a randomized complete block design with a generalized linear model where replicate and treatment were specified as fixed effects and initial weight was a covariate. Contagious variables were analyzed with a linear model while morbidity, mortality and feeding behavior were evaluated in a logit model.

Results: Significant differences were noted from initial processing to re-implant for weight gain. The CB and CS groups had smaller weight gains than the control group but were not different from each other. There were no differences in weight gain between treatments from placement to harvest. A significantly higher proportion of the CB group approached the bunk than the control group. There were no differences in morbidity or mortality between treatment groups and previous morbidity did not affect growth during the study period.

Conclusions: Castration or castration method did not influence performance over the entire feeding period or behavior in the immediate period after processing. These data suggest that both castration methods when performed greater than 30 days after placement produce similar objective outcomes.

BH-019-005

Detection of bovine respiratory disease (BRD) in feedlot cattle using multiple health-monitoring systems

Edouard Timsit ^{1,2,*}, Afra Verena Mang ³, Calvin W. Booker ², Trevor Alexander ⁴, Rene Quiniou ⁵

¹Production Animal Health, University of Calgary, Faculty of Veterinary Medicine, Calgary, ²Feedlot Health Management Services, Okotoks, ³University of Calgary, Faculty of Veterinary Medicine, Calgary, ⁴Agriculture and Agrifood Canada, Lethbridge, Canada, ⁵Institute for Research in Computer Science and Random Systems (INRIA), Rennes, France

Objectives: Accurate identification of sick cattle is key for effective bovine respiratory disease (BRD) control in feedlots. Unfortunately, current methods of BRD detection lack sensitivity (Se) and specificity (Sp) for detecting BRD. Monitoring systems that enable measurements of body temperature, feeding behaviour or physical activity could overcome this problem.

The objectives were to determine the Se and Sp of changes in body temperature, feeding behaviour or physical activity for BRD detection and to identify patterns that are both Se and Sp for BRD, based on simultaneous changes in body temperature and/or feeding behaviour and/or physical activity.

Materials and Methods: 561 crossbred beef steers at high risk of developing BRD (initial body-weight = 246 ± 45 kg) were observed during the first 50 days (d) after arrival at a commercial feedlot. Steers were equipped with (i) rumen temperature boluses to monitor body

temperature and (ii) three-axis accelerometers to monitor physical activity and feeding behaviour (specific system that detects the presence of accelerometers at the feedbunk). Steers with visual signs attributable to BRD (identified by pen checkers) were examined by a veterinarian. For each steer examined for BRD, 1 apparently healthy steer was selected as control and similarly examined. Serum haptoglobin (Hap) concentration was determined for each case and control. Steers with visual signs attributable to BRD, abnormal lung sounds at auscultation, and a serum Hap ≥ 0.25 g/L were defined as true positive BRD cases. Steers visually selected as controls with no abnormal lung sounds and a serum Hap < 0.25 g/L were defined as true controls. Data from health monitoring systems were retrospectively analyzed at the end of the study period using Cumulative Sum (CuSum) algorithms to detect significant behavioural and physiological changes. Se and Sp were calculated for each change alone and combined. The total number of changes detected per animal by CuSum algorithms during the 50 d study period was also calculated for each parameter alone or in combination.

Results: 34 and 26 steers were defined as true positive BRD cases and true controls, respectively. Increased body temperature was the most accurate to correctly classify true BRD cases and controls (Se = 87%; Sp = 96%); followed by decreased time at the feedbunk (Se = 71%; Sp = 71%) and decreased number of steps per d (Se = 60%; Sp = 71%). Increased body temperature was also the first to be detected with significant increases detected on average 56 h (min = 8; max = 164) prior to detection by pen checkers. During the 50 d study period, numerous changes were detected by CuSum algorithms with, on average, 4.4 (± 2.1) events of increased body temperature detected per steer, 7.7 (± 2.3) events of decreased number of steps per d and 2.3 (± 1.0) events of decreased time at the feedbunk. However, combining multiple parameters significantly decreased the number of events identified. The best combination was increased body temperature, and either decreased number of steps per d or decreased time at the feedbunk, with a Se = 83% and Sp = 96% and, on average, 2.4 (± 1.3) events detected per steer.

Conclusions: The most Se and Sp parameter to detect BRD was increased body temperature. This parameter should nevertheless be combined with other parameters such as decreased number of steps or decreased time at the feedbunk to reduce the number of detections per steer. These findings create an impetus to build new systems that simultaneously monitor multiple parameters including body temperature, number of steps per d and time spent at the feedbunk.

BW-025-001

The effect of NSAID and disbudding method on calves' behavior

Juha Hietaja^{1,2} Suvi Taponen³ Matti Pastell^{2,4} Marianna Norring²
³Tiina Kauppinen^{2,3} Laura Hanninen^{5,6,*}

¹Agricultural Sciences, ²Research centre for animal welfare, ³Production animal medicine, University of Helsinki, ⁴Natural Resources Institute Finland, Helsinki, ⁵Research centre for animal welfare, ⁶Production animal medicine, University of Helsinki, University of Helsinki, Finland

Objectives: Disbudding causes pain, but the needed length of post-operative pain medication or the possible differences between disbudding with heat cauterization and caustic paste are not known. Changes in calf activity and milk-feeder usage could be used as a measure for the calves' coping with the pain after disbudding. We studied the differences between disbudding methods and the effect of prolonged treatment with a non-steroidal anti-inflammatory drug (NSAID) on dairy calves' activity and milk-feeder visits.

Materials and Methods: We performed a 2*2 factorial design study on two-week old dairy calves weighing (mean ± SE) 51±1 kg. We disbudded calves during sedation with either heat cauterization (CAUT n=24) or caustic paste (PASTE n=23). CAUT calves were also given local anaesthesia (lidocain). All calves got NSAID (ketoprofen) orally (4 mg/kg) before sedation (detomidine), and the NSAID5 during four more days (n=24). NSAID1 got equivalent volume of water (n=23). All calves were sham-disbudded 2 days prior (day-2) disbudding (day 0). We registered calves activity and milk-feeder visits with accelerometer and automatic-milk-feeder from day -2 to day 8. Calves were weighed days -2, 0, and 10, and calculated number of nutritive and non-nutritive visits, consumed milk, and number and duration of resting bouts and total durations for daily resting and activity. The differences between treatments were analysed with repeated sampling linear mixed models.

Results: NSAID tended to decrease daily overall activity (p<0.06): NSAID5 spent less time active than NSAID1 (473±24 vs. 530±22), and NSAID5 were lying down daily longer NSAID1 calves (1022.6 ± 18 min vs. 1002.11± 18 min, p<0.05). Treatment*disbudding interactions were found for the mean number and bout length of lying behavior (p<0.05 for both): NSAID5+CAUT calves lie down daily more often than the NSAID5+PASTE calves did (22±1 vs. 19 ±1), but NSAID5 +PASTE calves had longer lying bouts than NSAID5+CAUT calves (55.43 ± 5.0 min vs. 47.78 ± 5.0 min). Treatment*day interactions were found for the number of all and non-nutritive feeder visits (p≤0.05 for all): NSAID5 had more visits than NSAID1 on days 3 and 4 (19±1 and 14±1 vs. 16±1 and 12±1, respectively) and non-nutritive visits on day 3 (10±1 vs. 5±1). CAUT calves drank milk portions quicker than PASTE disbudded ones (0.7±0.03 l/min vs. 0.6±0.03 l/min; p=0.015). No statistically significant growth-effects were found, nor did amount of consumed milk differ

Conclusions: Disbudded calves seem to benefit from a five-day NSAID medication, as it reduced restless behaviour and increased number of feeder visits. Caustic paste calves also had a decreased drinking speed, with no effect of NSAID. We suggest that chemical and mechanical burn causes different pain after disbudding, on which NSAIDs effect differently: NSAID increased bout lengths for caustic paste disbudded calves and number of lying bouts for heat cauterized calves.

BW-025-002

A model for identifying dairies with poor welfare using a national cattle registration database

Catarina Krug^{1,2,*} Marie J. Haskell³ Telmo Nunes⁴ George Stilwell¹

¹Centro de Investigação Interdisciplinar em Sanidade Animal, Faculdade de Medicina Veterinária, Universidade de Lisboa, Lisboa, Portugal, ²Département de pathologie et microbiologie, Faculté de médecine vétérinaire, Université de Montréal, St-Hyacinthe, Canada, ³Scotland's Rural College, Edinburgh, United Kingdom, ⁴CIISA/UISEE/DETS, Faculdade de Medicina Veterinária, Lisboa, Portugal

Objectives: Consumers are increasingly demanding that the welfare of food animals is regulated. Welfare assessment protocols have been created based on scientifically valid principles. However, most on-farm welfare assessment protocols are time-consuming and expensive and there are concerns about whether they can feasibly be implemented in practice. The objective of this study was to determine whether dairy farms with a high risk of poor welfare could be identified from a national cattle database, therefore reducing the number of welfare audit visits that must be made.

Materials and Methods: The welfare of dairy cattle was assessed using the Welfare Quality (WQ) protocol on 1,930 adult animals from 24 Portuguese dairy farms. After identifying the farms with poor welfare (level 'not classified' according to the Welfare Quality protocol), 15 potential national welfare indicators were calculated based on a national cattle database (Sistema Nacional de Identificação e Registo de Bovinos, SNIRB) that contained data on births, herd movements and records at slaughter. The link between the results on the Welfare Quality evaluation and SNIRB was made using the identification code of each farm. To evaluate the probability of a farm having poor welfare, we created a decision tree using the classifier J48 of Waikato Environment for Knowledge Analysis (WEKA).

Results: Five farms were classified as having poor welfare ('not classified'), and the other 19 as having good welfare (18 'acceptable' and one 'enhanced' according to the WQ protocol). From 15 potential national welfare indicators from the national database, only two were significantly different between farms with good welfare and poor welfare. These variables were proportion of on-farm deaths (p < 0.01) and female/male births ratio (p < 0.05). The decision tree was based on the indicators proportion of on-farm deaths and proportion of calving intervals higher than 430 days to identify farms with higher risk of having poor welfare. Using this model, it was possible to correctly identify 70% and 79% of the farms classified as having poor and good welfare, respectively.

Conclusions: This study allowed for the development of a model to identify herds with poor welfare through two variables: proportion of on-farm deaths and calving-to-calving interval. Further studies should be carried out to assess the reliability of these findings for other situations. National cattle databases may simplify dairy welfare evaluation through detection of farms with a higher risk of having poor welfare. This would allow the more time-consuming welfare quality audits to be performed only on farms that are more likely to be problematic.

BW-025-003

Primary versus secondary damage in downer dairy cows

Phil Poulton ^{1,*} Andrew Vizard ² Garry Anderson ³ Michael Pyman ²¹Tarwin Veterinary Group, Leongatha, ³95³, ²Faculty of Veterinary and Agricultural Sciences, The University of Melbourne, Werribee, Australia

Objectives: Downer dairy cows under commercial dairy farming conditions were monitored during their recumbency, and the importance of the primary cause of their recumbency on outcome was investigated in comparison to the effect of any secondary complications. This research was aimed at advancing the understanding of down cows, and to help improve animal welfare.

Materials and Methods: Downer dairy cows, as defined as bright and alert cows that had been recumbent for more than one day, were monitored during their recumbency under field conditions in South Gippsland, Victoria, Australia. It was an observational study of the ways farmers managed their down cows, and the 'intention to treat' was not the same for each cow. The research took place over two consecutive three-month winter seasonal calving periods in 2011 and 2012. The cause of the original recumbency of the cows was determined and allocated into one of five groups: post parturient hypocalcaemia (milk fever), protein-energy deficiency, calving paralysis, back injury or 'other'. Any secondary damage that occurred was recorded and determined if it was 'clinically important'. Status on day 7 and final outcome were recorded. For those cows that did not recover, a clinical judgement was made as to whether their demise was due solely to the primary cause of their recumbency, the secondary damage or a combination of both.

Results: There were 218 dairy cows on 96 dairy farms that fitted the study criteria. By day 7, 52 (24%) cows had recovered and 69 (32%) cows eventually recovered. The calving paralysis group was the largest group, comprised of 98 (45%) cows. When it was used as the reference group for day 3, 5, 7 and final recovery there was no significant overall effect of primary damage group ($P = 0.43, 0.44, 0.19$ and 0.41 , respectively). Some type of secondary damage was found in 183/218 (84%) cows, of which 173/218 (79%) had damage deemed to be clinically important. There were 25 different types of secondary damage recorded and 101 (46%) cows had more than one type of damage concurrently. The day 7 recovery for cows without any secondary damage was 57% (20/35 cows) compared to 14% (25/173 cows) with clinically important secondary damage (OR 7.9; 95% CI 3.6-17.4; $P < 0.0001$). Of the 149 (68%) cows that were euthanased or died, 23 (15%) were deemed to have been lost solely from the primary cause, 107 (72%) from secondary damage and 19 (13%) from a combination of both.

Conclusions: It was shown that once cows had been recumbent for more than one day there was no difference in recovery between the five primary causative groups. Clinically important secondary damage occurred very commonly and was shown to decrease the odds of recovery at day 7 by nearly eight-fold compared to cows that did not suffer any secondary damage. It was found that for the majority of the cows that did not recover, the secondary damage was more important in determining their fate than the initial cause of their recumbency. These are important findings for the welfare of downer cows.

BW-025-004

The influence of the quality of nursing care on recovery in downer dairy cows

Phillip Poulton ^{1,*} Andrew Vizard ² Garry Anderson ³ Michael Pyman ²¹Tarwin Veterinary Group, Leongatha, 3953, ²Faculty of Veterinary and Agricultural Sciences, The University of Melbourne, Werribee, Australia

Objectives: Research was undertaken to investigate if the level of nursing care had an influence on the occurrence of secondary damage and on outcome in recumbent dairy cows. If so, these findings could be used to develop guidelines for 'best practice' management of down cows.

Materials and Methods: Downer dairy cows, as defined as bright and alert cows that had been recumbent for more than one day, were monitored during their recumbency under field conditions in South Gippsland, Victoria, Australia. It was an observational study of the ways farmers managed their down cows and the 'intention to treat' was not the same for each cow. The research took place over two consecutive three-month winter seasonal calving periods in 2011 and 2012. The cause of the original recumbency of the cows was determined and any secondary damage that occurred was recorded. All of the factors associated with their nursing care were recorded and a four-tiered grading system describing nursing quality, ranging from Score 1 (excellent) to Score 4 (very poor), was developed to allow analysis of its influence on outcome and on occurrence of secondary damage. The nursing grade was assigned at the completion of the recumbency on the basis of the criteria but without consideration of the outcome. Nursing Score 1 and 2 were combined to form the category 'satisfactory' nursing and Nursing Score 3 and 4 combined to form the category 'unsatisfactory nursing' for some analyses. The Cochran-Armitage test for trend was used to test for a linear component of trend between nursing scores and the proportion of cows with a given binary outcome.

Results: There were 218 dairy cows on 96 dairy farms that fitted the study criteria. By day 7, 52 (24%) had recovered and 69 (32%) eventually recovered. Some type of secondary damage was found in 183/218 (84%) cows, of which 173/218 (79%) had damage deemed to be clinically important.

There was a strong linear trend of increased day 7 recovery with increased level of overall nursing care ($P = 0.001$). There was a strong association between the occurrence of clinically important secondary damage and a decreasing level of overall nursing care ($P < 0.001$). As nursing care decreased from Score 1 to Score 4 there was a decrease in the percentage of cows recovering by day 7 from 33 to 0%, a decrease of cows eventually recovering from 45 to 0%, and an increase of cows suffering clinically important secondary damage from 68 to 100%. Some of the cows nursed 'satisfactorily' continued to recover even up to 27 days of recumbency whereas no cows nursed 'unsatisfactorily' recovered after day 5.

The level of nursing care in the study area was found to be generally sub-standard with 102/218 (47%) cows judged to be nursed 'unsatisfactorily' when first attended by the primary researcher and 67/218 (31%) nursed 'unsatisfactorily' overall.

Conclusions: The study concluded that the occurrence of secondary damage and recovery was strongly associated with the level of nursing care in downer cows. The standard of care provided by farmers in the study was often sub-standard, highlighting the need for better education of farmers, veterinarians and industry advisors in relation to nursing care. This would be expected to lead to improvements in animal welfare. The study recommends that if downer cows cannot be nursed under high levels of care, for any reason, they should be promptly euthanased to avoid unnecessary suffering as their chance of recovery is very low.

BW-025-005

A single prolonged milking interval of 24 hours compromises the well-being and health of dairy Holstein cows

Philipp Kohler ^{1,*}, Maher Alsaad ¹, Gaudenz Dolf ², Robert O'Brien ³, Gian Beer ¹, Adrian Steiner ¹

¹Clinic for Ruminants, ²Institute of Genetics, Vetsuisse-Faculty, University of Bern, Bern, Switzerland, ³Department of Veterinary Clinical Medicine, University of Illinois, Urbana, United States

Objectives: Cows at dairy cow shows are often presented with overfilled udders in order to get a better ranking by the show judges. However, it is unclear to what extent this over-bagging during cow shows affects cows' health and well-being. Therefore, the goal of this study was to assess the effect of a single prolonged milking interval (PMI) of 24h on health and well-being of dairy cows in early- and mid-lactation and to assess the effect of a non-steroidal anti-inflammatory drug (NSAID) during a PMI of 24h.

Materials and Methods: Fifteen Holstein cows were studied in early lactation in a cross-over design and were administered NSAID and physiologic saline solution, respectively. Ten of these cows were studied again in mid lactation. Data were collected during a base line period of 24h and during a PMI of 24h in one or two hour intervals. Data of feeding and locomotion behaviour were collected using the RumiWatch®-System (consisting of a three dimensional pedometer and a noseband sensor). Udder firmness and weight distribution were measured by using a dynamometer and a four platform weighing scale, respectively. The abduction of the hind limbs was assessed while standing (indirect measurement of abduction by analysing digital images) and walking (subjective score; 0-100). Occurrence of milk leakage and oedema formation in the subcutaneous udder tissue was assessed by visual observation and ultrasound examination, respectively. Data of the last 6h of a 12h milking interval were compared with the last 6h of the PMI.

Results: The behaviour of cows in early lactation (without NSAID) was significantly changed during the last 6h of PMI, as we observed decreased eating time, increased ruminating time and hind limb abduction while walking and standing. Udder firmness was increased during this period and relatively more weight was placed on the hind limbs. Pathological signs were found at the end of PMI: 100% of cows showed milk leaking and two thirds of cows developed oedema in the subcutaneous udder tissue.

Administration of NSAID did not influence variables substantially, except for oedema formation, which was not significantly increased during PMI in the NSAID-group. In the cows in mid-lactation, different variables were no longer significantly changed (e.g. eating and ruminating time, occurrence of oedema and the abduction during walking).

Conclusions: It is concluded that cows' health and well-being are compromised by a single PMI of 24h, as the behaviour is changed (decreased eating time, increased ruminating time and hind limb abduction) and different pathological signs were recorded (oedema in subcutaneous udder tissue and increased milk leakage). NSAID had only a slight effect on the well-being of cows during a PMI. Otherwise, a single PMI has less effect on the well-being of cows in mid-lactation, as fewer variables were changed significantly as compared to cows in early lactation.

BW-025-006

Practices for the disbudding and dehorning of dairy calves by veterinarians and dairy producers in Ontario, Canada

Charlotte Winder ^{1,*}, Stephen J. LeBlanc ¹, Derek B. Haley ¹, Kerry D. Lissemore ¹, M.A. Godkin ², Todd F. Duffield ¹

¹Population Medicine, University of Guelph, ²Ontario Ministry of Agriculture, Food and Rural Affairs, Guelph, Canada

Objectives: The objective of this study was to build on a 2004 survey of bovine veterinarians and dairy producers in Ontario (Misch et al., 2007), to determine if disbudding and dehorning (DD) practices had changed over the past decade, and to examine factors associated with the adoption of pain-control.

Materials and Methods: An online survey (Qualtrics, 2005. Provo, UT), with an option to participate via telephone, was conducted in the fall of 2014. Members of the Ontario Association of Bovine Practitioners (n=238), and a subset of Ontario dairy producers (n=603, stratified by 15 geographic zones) were invited to participate. Both surveys included the following sections: demographics, DD practices including use of pain control, perceptions of pain, and knowledge of the Canadian Code of Practice for the Care and Handling of Dairy Cattle. The producer survey also included questions on use of polled genetics, and general calf management.

Perceptions of pain were evaluated by use of an ordinal Likert scale, with 0 being no pain, and 10 being the worst pain imaginable. Both producers and veterinarians were given the same eight procedures/conditions cattle may experience, and asked how painful they thought the animal would be, assuming no anesthetics or analgesics were given unless stated otherwise. The eight procedures/conditions were: dystocia (hard pull), severe mastitis, sole ulcer, right flank surgical correction of left displaced abomasum (with a local block given), ear tagging at birth, caustic paste applied at two days of age, small diameter thermal disbudding at two weeks of age, and surgical amputation and cautery dehorning at five months of age.

Results: Ninety-three veterinarians (39%) from 51 clinics (63%) and 165 dairy producers (27%) completed the survey.

Ninety-four percent of responding clinics reported veterinarians or veterinary technicians perform DD for a mean of 29% (SD=20) of their dairy clients. Compared to the 2004 veterinary survey, significant increases were seen in the use of local anesthetic (99% vs. 92%, p=0.013) and NSAIDs (59% vs. 1.5%, p<0.001). Injectable meloxicam represented 89% of all NSAIDs used.

Dairy producer respondents had a mean age of 44 years old (SD=13, range=16-74). Farms had from 20-450 milking cows (mean=82, SD=71). Seventy-three percent of farms performed DD themselves. Of these, 62% used local anesthetic, 38% used sedation, and 24% used an NSAID. The use of all three medication types was significantly greater than 2004. Sixty-three percent of producers reported changing DD practices in the past 10 years. Common changes included addition of local anesthetic (60%) and performing DD at a younger age (30%). The most common influence cited for changes was the herd veterinarian (73%).

Factors associated with use of local anesthetic by producers were assessed in a logistic regression model. Positive associations included: herd health visits every two weeks or sooner (OR=3.9, p=0.018), and increasing % of calves DD at >8 weeks of age (OR=1.01, p=0.045).

Differences in likert scores between veterinarians and producers were evaluated for all 8 procedures/conditions. There were no differences in median score (Hodge Lehman median difference test) or equality of distribution (Kolmogorov-Sminrov test).

Conclusions: The use of local anesthetic in this survey was far higher than previously reported. NSAID use by veterinarians was also far higher than previously reported. Within the survey populations, producers and veterinarians appeared to view the experience of pain by cattle similarly. A strong relationship between producer and veterinarian was associated with the adoption of pain-control. Veterinarians can clearly play a key role in improving DD practices for dairy calves. Identifying factors associated with adoption of best practices may help veterinarians target appropriate educational opportunities for their dairy clients.

BV-033-001

From control to surveillance – the Swiss Bovine Viral Diarrhoea (BVD) eradication programme

Heinzpeter Schwermer ^{1,*}Elena Di Labio ¹¹Animal Health, Federal Food Safety and Veterinary Office FSVO, 3003 Berne, Switzerland

Objectives: We inform about the experiences from the Swiss Bovine viral diarrhoea (BVD) eradication programme. In the programme the shift from control to surveillance continued in the last few years. We show the relative importance of case measurements and measurements on farms known to have a higher risk for BVD persistence and re-infections compared to large scale testing. We discuss possibilities to keep the time period with low frequency cases (epidemic tail), following the main clearance, short.

Materials and Methods: In animal disease eradication programmes, determining the time point to shift from control to surveillance is of crucial importance for the effectiveness and the economy of the programme. As control comprises usually large scale testing, it should be as short as possible. Therefore, the shift to surveillance should take place as early as possible. On the other hand, shifting too early to surveillance increases the risk of leaving new infections unrecognized. Traditionally, the shift is done following an extended time of control testing without revealing any cases. In BVD programmes time intervals are long. Thus, there is often a need to change to surveillance even in the presence of new infections.

The Swiss BVD control programme was based on the detection and elimination of persistently infected animals. This was done by testing for antigen or by PCR. After virological testing of all cattle, all newborn calves have been tested for BVD virus for 4 years until the end of 2012. In 2012, serological tests twice a year of all dairy herds and of a third of the remaining farms was done additionally to calf testing. In 2016 the testing programme will be reduced to once per year for dairy herds whereas it will not change for other herds. However, as case numbers are low, but do not decrease further, measures to control case herds more efficiently are applied since autumn 2015.

We analyse the data from the BVD control programme descriptively, showing the rationale for lowering surveillance while increasing case control measures. We present examples for infection chains during control.

Results: In October 2015 only 30 herds out of a population of 40,089 cattle herds are closed due to BVD. About 99.9% of the herds are free from BVD. Only about 80 herds still have single cows blocked because of known or likely exposure to BVD cases during the susceptible pregnancy time. The prevalence of persistently infected animals (PI) in newborn calves has decreased from 1.4% in 2008 to 0.03% in autumn 2015. In spring 2015 96% of the dairy herds showed no or only few antibodies in bulk milk samples. Due to the surveillance scheme, the figures for non-dairy herds cannot be derived easily, but indicate the same trend. Varying causes were responsible for the prolonged persistence of BVD on a small scale. The causes depended on the testing scheme and the eradication phase. First, during the calf testing, some of the herds could not be cleared from BVD. This was caused by poor herd management and faults in sample taking. Second, when changing from calf testing to serological testing, bovines tested false negative for BVD virus caused some damage, although the absolute number of such animals was small. Third, in the phase of serological testing, problems arising from data inconsistencies in the animal movement database hindering effective tracing forward and backward and ambiguous herd identifying are the main problems. In 2015 we observed about 30 re-infections of herds previously free from BVD. Interestingly, about 95% of the cattle herds have been free from BVD throughout the whole programme.

Herds with a history of BVD were at higher risk to get re-infected.

Conclusions: For BVD eradication, it is of high importance to consider the weaknesses and strengths of the testing scheme and the eradication phase. During calf testing, prevention of within herd transmission is of major importance as is the true sensitivity of the whole sampling and testing chain. During serological testing, reliable data of animal movements and herd connections are of higher importance, as the time interval from infection to detection of affected herds is longer. In contrast, determining a BVD negative status of a herd from calf testing is not possible. Virustyping is of importance to investigate infection chains between herds.

BV-033-002

The Scottish BVDV Eradication Scheme: Are we making progress?

Helen Carty ^{1,*}George Caldow ²¹SAC Consulting: Veterinary Services, Ayr, ²SAC Consulting: Veterinary Services, St. Boswells, United Kingdom

Objectives: Over the past 20 years, BVDV control and eradication programmes have been used throughout Scotland, predominantly in the beef sector. Following extensive consultation, the Scottish Government considered that a national eradication scheme would benefit the cattle industry. The motives for eradicating BVDV included: improving the financial sustainability of cattle production; improving the welfare of cattle; and reducing greenhouse gas emissions per kilogramme of milk and beef produced by increasing the efficiency of production.

Materials and Methods: The Scottish BVDV eradication scheme has taken a phased approach. In phase 1, which ran from September 2010 to April 2011, the Scottish Government subsidised testing in order to encourage farmers to determine their BVDV status. Legislation was put in place for phase 2. This required all breeding herds to screen for BVDV by February 2013 and annually thereafter. Farmers and their veterinary surgeons could choose from one of six different testing methods: the antibody check test (spot test); calf screen for virus; whole herd screen for virus; or one of three options using bulk milk sampling for antibody. Further legislation was put in place for phase 3 in January 2014: the herd status had to be declared at the point of sale; movement restrictions were put on untested herds; and animals persistently infected with BVDV could only be moved directly to slaughter. Phase 4 commenced in June 2015. The number of screening options were reduced by the removal of the bulk milk testing methods. Movement restrictions were put on herds with a "not-negative" status and there are now testing requirements for animals entering herds from untested holdings.

Results: A survey carried out prior to the eradication scheme indicated that 40% of Scottish breeding herds had evidence of exposure to BVDV. The percentage of beef herds classified as "not-negative" has fallen from 23% in 2012 to 9% in September 2015. The percentage of dairy herds with this status has fallen from 52% to 31% in the same time period. Currently 12% of breeding herds in Scotland are classed as "not-negative". To date 3,128 animals have been identified as infected with BVDV; of these 514 are still alive on holdings in Scotland. BVDV results from all approved testing laboratories are held in a central database that is used by farmers, markets, veterinary surgeons and government.

Conclusions: The Scottish BVDV eradication scheme has made considerable progress over the past five years. The phased approach has ensured that all sectors of the cattle industry are aware of their increasing responsibilities. This progress is comparable with

Scandinavian countries that have taken a similar approach to eradication. In these countries this began with voluntary schemes and progressed to compulsory testing with eradication typically achieved in ten years.

BV-033-003

Results of the first year of the mandatory BVDV control program in Northern-Belgium

Stefaan Ribbens ^{1,*}, Jozefien Callens ¹, Willem Van Praet ¹, Eva van Mael ¹, Leen Van Schoubroeck ¹

¹Animal Health Care Flanders, 9031 Drogen, Belgium

Objectives: During decades, the control of bovine viral diarrhoea virus (BVDV) in Belgium was on a voluntary basis. Initiatives of eradication at the herd level were successful if well-performed, but the absence of a systematic form of control of BVDV resulted in a high risk of (re)-entry of the virus in all cattle herds in Belgium. Starting from the first of January 2015, a national BVD-program was initiated for Belgium. The main goal of the program 'STOP BVD', is to eradicate the virus. This abstract discusses the layout of the Belgium BVDV control program and gives the results of the first year of the program.

Materials and Methods: The pillar of the eradication program is to detect persistently (PI) infected animals in an early phase after birth. Similar to other European countries (e.g. Germany and Ireland), all newborn animals have to be tested for BVD-antigen, this within 7 days after birth. This systematic 'newborn testing' preferably happens through an ear notch sample taken by the farmer.

The results presented in this abstract are based on the national BVD-database which was installed and coupled with the I&R-database. Different states included in the program are: PI-free, PI-free by descendance, PI, and PI-suspect and BVD-state unknown. PI and PI-suspect animals are prohibited from trade, and PI-animals are encouraged to be culled. Animal BVD-states are listed on the animals ID and available for all farmers. In case of the detection of a PI, veterinarian herd visits to sample suspect animals and are encouraged to trace other PI animals at the farm, coupled with other measures to control BVD.

Results: The results presented in this abstract only include the first 11 months of the program. During this period, 440.447 newborn animals were tested for BVD-antigen using ear notch samples. 2.690 samples were empty (i.e. ear notch sampling unsuccessful) in which a new sample was taken by the herd veterinarian. 2.556 newborn calves tested positive and were classified as PI animals on 1.179 cattle herds in Northern-Belgium. Although in this stage of the program, culling of PI-animals remains voluntary, on average 90% of PI animals of newborn calves were euthanized. Through testing of the dams of this PI-animals, again 187 PI-dams were detected through sampling of the herd-veterinarian (i.e. about 10% of mothers of a PI-calf are itself a PI-animal). During the first year, another 359 PI animals were detected between 3 months and 2 years of age and another 381 detected PI animals were older than 2 years. The systematic testing of newborn animals coupled by the certification by descendance resulted that 957.045 cattle in Northern Belgium are certified as PI-free.

Conclusions: The results of the first year of the 'STOP BVD' program illustrates Belgium was in need for a systematic approach of BVDV-control. Approximately 6 out of 1.000 newborn calves were PI animals. PI-animals were detected 1.383 cattle herd or about 9.2% of cattle herds in Northern-Belgium. Through systematic testing of newborn animals, about 78% of cattle were certified PI-free for live.

BV-033-004

Application of epidemiological and economic modelling to the Irish BVD eradication programme

Hans-Hermann Thulke ^{1,*}, Michael L. Doherty ², David A. Graham ³, Martin Lange ¹, Jamie Tratalos ⁴, Guy McGrath ⁴, Luke O'Grady ², Padraig O'Sullivan ⁵, Simon J. Moore ⁴

¹Ecological Modelling, Helmholtz Centre for Environmental research - UFZ, Leipzig, Germany, ²School of Veterinary Medicine, University College Dublin, Dublin, ³Animal Health Ireland, Carrick on Shannon, ⁴UCD Centre for Veterinary Epidemiology and Risk Analysis, University College Dublin, Dublin, ⁵Irish Cattle Breeding Federation, Bandon, Ireland

Objectives: Bovine Viral Diarrhoea (BVD) is an infectious disease of economic importance across the world. The production losses in BVD-affected farms have motivated many national control programmes. In 2013 Animal Health Ireland (AHI) initiated the compulsory phase of the Irish national BVD eradication programme based on ear notch antigen testing of newly born calves. The objective of our study was to conduct a comparative epidemiological and economic assessment to understand the benefits and pitfalls of introducing herd level serological testing (Option 2) as an alternative surveillance strategy to individual animal virus testing (Option 1).

Materials and Methods: The comparative evaluation of surveillance strategies was performed with a spatially explicit herd-level simulation model. The model was tailored to represent the farm and national dimension of the Irish cattle sector. It comprises approximately 100,000 individual cattle farms, their location, size, management groups and breeding schedules, contiguity on land parcel level and the complete record of cattle movements between Irish farms replicated by source, target and age data. Farm behaviour related to the retention of PI animals was also included. Secondary patterns reported from AHI programme data were used to calibrate the model. The model was run for 5 years of BVD endemicity (i.e. corresponding to 2008-2012) followed by 10 years of control programme (i.e. 2013 onwards). The simulated measures utilised Option 1 for 3 years, continuing (i.e. from 2016) with either Option 1 or 2. The latter including a temporary return to virus testing on farms with a BVD positive diagnosis. Key model outputs included the number of farms with BVD, the number of calves detected as PI per year, the quantity of testing applied under the various control programmes, and assessment of pathways leading to breakdown of BVD negative farms e.g. 'Trojan' cow movement or across-the-fence transmission.

Results: If retention of detected PI calves was excluded, both surveillance options resulted in BVD eradication, with only a slight delay associated with Option 2. Costs of diagnostic testing differed at the national level and were lower for option 1 because a BVD breakdown in a herd using serological screening would require a return to tag testing for some years. The risk of farm breakdown declined as the programme progressed. There was a tipping point in cost ratio, depending on farm level prevalence, beyond which the expected future costs would favour Option 2.

However, when the level of PI retention, as reported from AHI programme data, was modelled, the simulation outcomes were less optimistic. Eradication was delayed with a doubling of the control time, or was not achieved within the 10 year time window of the simulation.

Conclusions: The retention of PI animals by some farmers is hindering the effectiveness of the simulated BVD control programme by lengthening time to eradication, increasing the cost of eradication and jeopardising control efforts on BVD-negative farms. In the absence of PI retention, in time it would become cost-effective to change from individual calf virus testing to a farm-level serological surveillance approach.

BV-033-005

Economic evaluation of bovine viral diarrhoea virus control activities worldwide: a systematic review

Veronika Richter¹ Clair L. Firth¹ Karin Lebl² Martine Trauffer¹ Monika Dzieciol³ Sabine Hutter¹ Johann Burgstaller⁴ Walter Obritzhauser¹ Beate Pinior^{1,*}

¹Institute of Veterinary Public Health, University of Veterinary Medicine Vienna, ²Güpfelringstrasse 33, ³Institute of Milk Hygiene, Milk Technology and Food Science, ⁴University Clinic for Ruminants, University of Veterinary Medicine Vienna, Vienna, Austria

Objectives: The primary aim of this study was to assess studies with a specific emphasis on the costs and benefits of control activities of the bovine viral diarrhoea virus (BVDV) at national, regional and farm level. The second aim was to collect data with respect to direct (production) losses and indirect losses caused by the costs of BVDV control, as well as to the net benefits and costs of these control activities. Furthermore, we hypothesized that countries for which estimates of production losses are recorded also carry out economic assessments of their control activities.

Materials and Methods: An extensive literature search covering research from 1970 to 2014 was performed between December 2014 and July 2015 using the online databases PubMed, ISI Web of Science and Scopus. The search term "BVDV" was combined with the keywords "control program/me", eradication, intervention, mitigation, surveillance, freedom of disease, biosecurity, Scandinavian strategy, "disease losses", cost analysis, cost benefit, economics, economic models, expenses and financial impact.

Each paper was first reviewed in full and the economic content (if available) was evaluated based on predefined economic assessment criteria ranked between high quality (1) and low quality (4). High quality studies include an economic analysis of control activities, the allocation of the costs and benefits per player as well as quantitative values of the economic assessment of control activities. The low quality studies do not include an economic analysis in their methods, but describe the economic outcome of their studies in passing and provide only qualitative values for control activities. All economically relevant studies (primary studies) were reviewed according to their location, assessment level (national, regional, industry, farm), aims, methodology, production types, metrics, outcomes and research field (e.g. epidemiology and risk; diagnostic and genomic analysis; vaccines and vaccination strategy). In the next step, the references of the primary studies were screened by title and abstract. Of these, all articles that were considered relevant were also reviewed in full (secondary studies).

Results: Overall, 29% (n=144) of the identified articles (N=501) included information on economic assessments of BVDV control activities. Of these 144 articles, approximately 18% could be allocated to national, 25% to regional, 27% to farm level and 30% to no explicit geographical category. The most frequent aim of these studies (33%) was to describe or evaluate the eradication/control programmes or prevention approaches, followed by the description, evaluation or development of diagnostic methods or approaches (20%). Studies with the highest quality levels of the economic assessments were found in the United Kingdom, Norway and France, and studies with good quality levels were identified in the United States, Switzerland, New Zealand, Netherlands, Ireland, Denmark and Canada.

In total, 50% of the studies made direct reference to cattle in general, with an additional 21% analysing dairy farms, 6% beef farms and 4% calves and youngstock. In the remaining 19%, no mention of bovine species or production type was made. Furthermore, 16% (n=80) of the studies provided data on direct losses due to reduced production.

The studies with high quality assessments were found in 23% and the majority studies were conducted on the farm level.

Conclusions: Our systematic review shows that most studies (69%; [99/144]) on BVDV provided only qualitative values of control activities and did not include an economic methodology in their study design. This lack of economic assessment is also visible in the calculation of the production losses. Our hypothesis that countries which record production losses are also likely to carry out economic assessments of control activities could not be confirmed in full. Some countries calculated production losses but did not provide an economic assessment of control activities or did not conduct systematic control activities against BVDV.

BV-033-006

The importance of the number of animals tested and threshold at which a herd is deemed positive for BVD when testing young-stock for BVDV antibodies.

Roger Humphry¹ Katie Adam¹ Jude Eze¹ George J. Gunn^{1,*} and Epidemiology Research Unit

¹SRUC, Inverness, United Kingdom

Objectives: The objective is to demonstrate some examples of why vets in practice should take into account the number of animals tested and the threshold of positives at which the veterinarian or, if it is part of a scheme, then the scheme decides to designate that herd as positive. It is likely that to some extent veterinarians do this intuitively but it is also useful to have quantitative estimates of this for reference.

Materials and Methods: Prior to the start of the BVD eradication scheme in Scotland, a random survey of Scottish beef herds was undertaken and blood samples from ten young stock per herd were tested for BVDV antibody. Using the results from this survey it was possible to randomly sample from the results to see how many of the herds would have tested the same way depending upon (a) the number of animals tested and (b) the threshold of positive animals at which a herd is deemed positive.

Therefore we are able to present evidence of the effective herd-level sensitivity and specificity across different combinations of the number of animals tested and thresholds chosen.

Many schemes aiming to eradicate BVD choose, as a pillar of the screening system, the testing of blood of ten young-stock animals for antibodies to BVDV. If one or more animals tests positive then the herd is deemed positive. In some herds, the number of young-stock animals available for this screening process is fewer than ten. This study makes use of data from a random survey of beef farms in Scotland, prior to the Scottish eradication scheme, to show that the number of animals tested and the threshold of positive animals at which a herd is declared positive has a hugely important effect on the overall herd level sensitivity and specificity of this method. Veterinarians should be aware of this when interpreting their results.

Results: The herd sensitivity (i.e. the probability of designating the herd as positive given that it is truly positive) is greatly dependent on both the number of animals tested and the threshold at which we call the herd as positive. Unsurprisingly the herd sensitivity goes up with the former and down with the latter and we employ graphs to demonstrate this pattern based on our specific estimates of those different scenarios.

The herd specificity (i.e. the probability of designating the herd as negative given that it is truly negative) behaves in a fairly similar but reverse manner and we employ graphs to demonstrate this.

Conclusions: Whilst many veterinarians and farmers, probably intuitively, account for both the number of animals tested and the number of animals testing positive for BVDV antibody when interpreting their results, it is possible to give some empirical evidence in order to estimate how they would do this in a more quantitative way and this may be of interest to vets, farmers or those planning eradication schemes.

eliminate interference of colostrum-derived specific antibodies with BVDV antigen detection.

Comments: This work has been accepted for publication by the Journal of Veterinary Diagnostic Investigation.

Current address for Prof. M. P. Reichel: School of Veterinary Medicine, City University of Hong Kong.

BV-033-007

Heat treatment of serum from calves PI with BVDV to remove interference of colostrum-derived specific antibodies with antigen detection by ELISA

Sasha R. Lanyon ^{1,*}Michael P. Reichel ²

¹School of Animal and Veterinary Sciences, University of Adelaide, Roseworthy, ²School of Animal and Veterinary Sciences, University of Adelaide, Adelaide, Australia

Objectives: Bovine viral diarrhoea (BVD) is one of the most prevalent and economically significant viral diseases of cattle worldwide. A range of diagnostic tools are available for the detection of both viral antigen. The antigen ELISA is a rapid, inexpensive and robust test that successfully identifies persistently infected (PI) cattle. However, the antigen ELISA is subject to interference from colostrum-derived specific antibodies in serum of neonatal and young PI calves. This study investigated methods to remove specific antibodies from serum samples and, therefore, reduce interference.

Materials and Methods: Serum samples containing BVDV antigen and/or specific antibodies were treated by methods adapted from More and Copeman (Trop Med Parasitol 1991;42:91-94): treatment with heat (boiling) with or without the addition of an equal volume 0.1M EDTA pH 4.5, 5.5, 6.5 or 7.5. Treated samples were centrifuged and the supernatant recovered. All treated and untreated samples were tested for detectable BVD viral antigen and specific antibodies by ELISA (IDEXX BVDV Serum/Ag Plus ELISA and IDEXX BVDV Total Ab ELISA, respectively). The optimal treatment was identified and applied to serum samples collected longitudinally from three PI and seven non-PI calves from the day of birth to five weeks of age. As above, all treated and untreated samples were tested for detectable BVD viral antigen and specific antibodies by ELISA.

Results: All treatments resulted in an increase in antigen signal and a decrease in detectable antibody levels. Optimal treatment was identified as heat treatment with the addition of an equal volume of 0.1M EDTA pH 5 ± 0.5, resulting in antigen signal recovery in excess of 90%. When applied to field samples collected longitudinally from three PI calves from birth until five weeks of age, all treated samples tested positive for antigen at all time points. By comparison, the same samples when untreated returned negative antigen results for between six days and four weeks post-colostrum ingestion. The vast majority (98.6%) of samples from non-PI calves collected after the day of birth tested negative for BVDV antigen. On the day of birth, four of seven non-PI calves returned (low) positive results.

Conclusions: Heat and EDTA treatment of serum samples presents an opportunity to improve performance of BVDV antigen ELISAs for testing of colostrum fed calves. Diagnostic sensitivity was improved, however, diagnostic specificity was decreased substantially on the day of birth. The data indicates that adjustment of the positivity threshold is appropriate and will result in excellent diagnostic performance. Further study on larger numbers of calves is warranted, but the results of this study indicate that treatment of serum samples has the potential to

CH-044-001

Them And Us: Understanding How Farm Consultants View The Veterinary Profession

A Survey Of 25 Farm Consultants In New Zealand

Andrew Bates ^{1,*}, Wendela Wapenaar ², Adrian Campbell ³, Robin Eggleton ³

¹Centre for Dairy Excellence, Vetlife, New Zealand, Geraldine, New Zealand, ²Faculty of Medicine and Health Sciences, University of Nottingham, Nottingham, United Kingdom, ³Vetlife Administration Support Office, Vetlife, New Zealand, Timaru, New Zealand

Objectives: In New Zealand, farmers often rely on the input of private agricultural consultants in transferring technical and scientific research findings into practical changes in farm management. These activities will involve interactions with other rural professionals including veterinarians. This study was designed to assess the attitude of dairy farm consultants to the role of vets on dairy farms and whether they viewed veterinary advice as impartial, free from commercial bias and central to farm productivity and profitability.

Materials and Methods: A survey was commissioned in 2014 by Vetlife (Vetlife Administration Support Office, 82, Sophia Street, Timaru) – a mixed veterinary business in the South Island of New Zealand – using Cinta Research Ltd (Havelock North, Hawke's Bay, New Zealand) - a quantitative and qualitative research service specialising in the New Zealand agricultural industry. A formal telephone survey was conducted with dairy farm consultants in the Canterbury and Otago regions delivering a full time, fee earning business advising farmers to explore their attitudes towards the veterinary profession.

As an introduction, descriptive data was collected on the business model of the consultant's practice and experience. The first part of the questionnaire contained questions designed to elicit either numerical answers which could be categorised as a continuous variable or used a Likert scale from one to five measuring agreement with a statement and yielding ordinal variables. The second part consisted of six questions, the unprompted answers to which were collated and matched to a series of non-disclosed categories for each question. The last three questions were designed to allow the capture of more general pre-prepared statements. Statistical analysis was carried out where appropriate to assess numerical answers and agreement with statements.

A pilot survey was carried out with a full time rural farm consultant outside the group selected for participation to ensure that questions were clear and unambiguous.

Results: Just over half (56%) of the respondents worked as sole practitioners and 43% as part of a larger group. The median working experience of the group was 3-5 years. The answers that were collated from 25 respondents indicated that whilst consultants respect veterinary advice they see themselves as the custodians of animal health expenditure on farms. This is seen as an expense to be controlled with successful animal health characterised by low expenditure. This view was held more strongly by consultants with more than five years of professional experience. Interventions by vets are seen primarily in terms of treatment of sick animals, provision of animal health products and not as key drivers of farm profitability. Consultants feel they engage widely with farmers with major roles in the influence of animal health on farm productivity, nutrition and reproduction. They believe that animal health is a driver of productivity but they do not believe that veterinary led expenditure on animal health will deliver increased profitability.

Conclusions: Consultants are ambivalent about the value of working more closely with vets and about the benefit that closer veterinary intervention brings to the farm's profitability. For farm vets, better identification of farm goals, more team work with other rural professionals

and a wider understanding of the impact of veterinary actions at the farm level may help them to break down these barriers. Better understanding of how other rural professionals involved in a farm's management view vets will help to develop more successful veterinary involvement on farms, characterised by a deep understanding of the individual farmer's goals and motivations.

CH-044-002

Comparative losses due to liver fluke (*Fasciola hepatica*) in key sectors of the British cattle industry.

Sue C. Tongue ^{1,*}, Carla Correia-Gomes ¹, Jude I. Eze ¹, Madeleine K. Henry ¹, Alistair W. Stott ², Cath E. Milne ²

¹Epidemiology Research Unit, SRUC, Inverness, ²Future Farming Systems, SRUC, Edinburgh, United Kingdom

Objectives: Liver fluke is a common, ubiquitous parasite that affects the health and welfare of cattle worldwide. The costs incurred, via production losses and liver condemnations, and their effects on the economics of the British cattle industry are not entirely clear. In order to effect change and reduce reliance on drugs, we must demonstrate that any improved means to control the disease and reduce infection cost less than the benefits accrued from their application. Our objective was to develop bio-economic models that provide quantitative estimates of the losses incurred in alternative cattle production systems, as a first step in this process.

Materials and Methods: Herd-level stochastic models for growing animal, beef suckler herd and dairy enterprises were developed and implemented using @Risk. Each of these models can be modified to simulate the major management systems used (e.g. spring/summer calving suckler herd vs autumn/winter calving suckler herd) and, in the case of the dairy model, to account for a range of average 305-day milk yield per cow of between 5500 and 9000 litres. Linked to partial-budget models, they have been run for fluke vs. no fluke. Variables were parameterised with estimates derived from a variety of sources including: literature, publically available data, industry and expert opinion. Sensitivity analysis was performed to identify the most influential parameters in the models

Results: Spring/summer calving suckler herds have higher losses per infected cow than those calving in autumn/winter. In the growing animal model, spring/summer calving born beef replacement heifers herds have higher losses per infected animal than those born in autumn/winter; however the average loss per infected animal (£/year) is lower for spring/summer born beef finishers than others. Higher losses are experienced for growing heifers originating from suckler herds than from dairy herds. Dairy herd losses increase with increased milk yield; the median overall loss per infected cow is £186/year (range minimum in low yield herds £149-261 maximum in high yield herds). The main drivers differ between the models but reduction in performance parameters (e.g. milk production in the dairy model, average daily live weight gain in the growing animal model) and prevalence of fluke infection feature commonly.

Conclusions: We concluded that, at herd-level, liver fluke has a significant financial effect and we need better estimates of the effect that control methods have on the prevalence of infected animals. Outputs from these models will be aggregated to estimate national/regional net benefits of improved control of fluke of use for policy decision support. In later stages of the work, the suite of models will also provide a means to rank (by cost-benefit) potential control measures based on improved management practices.

CH-044-003

The costs of dairy production disorders in European practise; over- or underestimated?

Felix J. Van Soest ^{1,*}, Mariska van der Voort ¹, Monique C. Mourits ¹, Henk Hogeveen ^{2,3}

¹Business Economics Group, ²Business Economic Group, Wageningen University, Wageningen, ³Department of Farm Animal Health, Faculty of Veterinary medicine, Utrecht University, Utrecht, Netherlands

Objectives: For veterinarians and animal health advisors to give a good advice to the dairy farmer it is vital that the costs of disease are estimated correctly. Failure to do so may lead to wrong priorities in animal health management advice. The first objective of our study was thus to explore the costs of mastitis, lameness, ketosis and metritis as estimated in practise by farmers, veterinarians and animal health advisors. The second objective was to estimate the costs of each disease using a disease costs estimation tool. The third objective was to study whether farmers, veterinarians or advisors tended to over- or underestimate the costs of disease.

Materials and Methods: A total of 60 German, 21 Spanish and 40 Swedish organic dairy farmers were asked to participate in this study and to make their herd health records available for the cost estimations. The veterinarian and farm health advisor of each participating farm were asked to participate along with the farmer to calculate the farm specific cost. This study was part of a larger study on the improvement of animal health on organic dairy farms in Europe (IMPRO, 7th Framework).

To estimate the disease costs of mastitis, ketosis, lameness and metritis a cost estimation tool was constructed. In which disease costs comprised the following parts; milk production losses, discarded milk, treatment, culling and destruction. Technical model input included: number dairy cows, number of cases of clinical mastitis, SCC, fat/protein ratio, treated cases of ketosis, number of culled or death cows. Economic model input included: milk price, feed costs, costs of labour, slaughter value, replacement value, penalties paid and bonuses missed. For each economic input value a country specific reference value was given.

During each farm visit farmers, veterinarians and advisors were first presented with the overall performance of the dairy herd (e.g. milk yield, number of cows) and current health situation (e.g. number of (sub)clinical cases, SCC and lameness scores) and asked to estimate the total costs for each disease separately and solely based on these records. Second the costs estimation tool was performed and results were presented and discussed with the farmer, veterinarian and advisor.

Results: A total of 60 German, 21 Spanish and 40 Swedish farm visits were performed. In which, respectively 35, 28 and 40 German, 13, 15 and 7 Spanish and 27, 16 and 21 Swedish dairy farmers, veterinarians and advisors participated. The remaining participants did not estimate the costs of disease since they felt not qualified to estimate these costs.

The costs of mastitis on herd level were assessed by the disease costs estimation tool, at an average of €8,050 /yr., €10,613 /yr. and €11,099 /yr. for German, Spanish and Swedish farms. The costs of lameness were assessed at an average of €4,579 /yr., €2,565 /yr. and €3,357 /yr. for German, Spanish and Swedish farms. The costs of ketosis were estimated at an average of €2,152 /yr., €345 /yr. and €2,405 /yr. for German, Spanish and Swedish farms, respectively. The costs of metritis were estimated at an average of €2,060 /yr., €477 /yr. and €460 /yr. for German, Spanish and Swedish farms, respectively.

Over- and underestimating the costs of each disease by more than 50% of the assessed costs was found to be a common practice among farmers, veterinarians and advisors. The costs of mastitis, lameness, ketosis and metritis were on average underestimated by more than 50% in respectively 32%, 40%, 49% and 40% of all cases and overestimated

by more than 50% in respectively 19%, 23%, 27% and 45% of all cases. During a farm visit, farmers, veterinarians and advisors gave estimates which were, generally, in-line with each other's response.

Conclusions: Disease costs varied substantially within a country due to different input, either economic or technical. The farmers, veterinarians and advisors were found to either overestimate or underestimate the costs of production disorders by a substantial amount. Besides, some farmers, veterinarians and advisors found themselves unqualified to estimate the costs. Because economic arguments are, at least partly, a reason to adopt preventive measures or not, these results stress the importance to use a structured framework when estimating the costs of production disease on-farm, before advising preventive measures.

CH-044-004

Expert opinion disability weights for the Dairy Disease-Adjusted Lifetime (DAL) metric

Craig McConnel ^{1,*}, Joleen Hadrich ², Ashleigh McNeil ¹, Jason Lombard ³, Franklyn Garry ¹, Jane Heller ⁴

¹Clinical Sciences, ²Agricultural and Resource Economics, Colorado State University, ³USDA:APHIS:VS, Center for Epidemiology and Animal Health, Fort Collins, United States, ⁴Animal and Veterinary Sciences, Charles Sturt University, Wagga Wagga, Australia

Objectives: Over the past 175 years, data related to human disease and death have progressed to a summary measure of population health, the Disability-Adjusted Life Year (DALY). As dairies have intensified there has been no equivalent measure of the impact of disease on the productive life of animals. The development of a disease-adjusted metric requires a consistent set of disability weights that reflect the relative severity of important diseases. The objective of this study was to elicit dairy disability weights to be used in an assessment of the burden of disease on animal well-being and consequent opportunity costs of reduced productive life.

Materials and Methods: National and international dairy health and management experts were contacted through professional organizations, dairy industry publications and conferences, industry contacts, and word-of-mouth. Estimates of minimum, maximum, and most likely disability weights were established for calving trauma, diarrhoea, ketosis, lame (hoof only), left displaced abomasum, mastitis, milk fever, metritis, musculoskeletal injury (leg, hip, back), pneumonia, retained placenta, and right displaced abomasum. Survey participants were asked to rank the impact of each disease on overall health and milk production. Diseases were classified from 0 (no adverse effects) to 10 (death). The respective weights were dependent upon the estimated duration of clinical and subclinical disease inclusive of periods of treatment and recovery. The expert data was modelled using modified BetaPERT distributions to demonstrate the variation in these dynamic disease processes, and to identify the most likely aggregated disability weights for each disease classification. The PERT distribution was specified for each set of expert opinions (minimum, most likely, maximum), using the following formula: $PERT(a,b,c) = Beta(\alpha_1, \alpha_2) * (c-a) + a$. The individual distributions were combined using a discrete distribution in the form of $Discrete(\{x_i\}, \{p_i\})$, where $\{x_i\}$ were the expert opinions for experts $i = 1$ to n and $\{p_i\}$ were the equal weights given to each expert opinion.

Results: A total of 96 experts responded with estimates of disability weights. Veterinarians comprised the majority of respondents (83%), and most respondents were within North America (89%). The results indicated the following ranking of disease from least to most severe using

an average of the medians with the minimum, most likely, and maximum medians in parentheses: retained placenta (2, 3, 6), diarrhea (1, 3, 8), ketosis (2, 4, 8), metritis (2, 4, 8), mastitis (2, 4, 10), milk fever (2, 4, 10), lame (2, 5, 9), calving trauma (2, 5, 10), left displaced abomasum (4, 5, 9), pneumonia (3, 5, 10), musculoskeletal injury (3, 6, 10), and right displaced abomasum (4, 7, 10). The peaks of the probability density functions indicated that for certain disease states there was a relatively narrow range of expected impact whereas other diseases elicited a wider breadth of impact. For example, although mastitis and milk fever had equivalent overall distributions, the experts' average distribution width was narrower for milk fever than for mastitis. This suggests that for certain diseases such as milk fever, experts were confident about their estimate with the minimum, most likely and maximum scores closely aligned per respondent. For other diseases, it is likely that a more nuanced definition of disease with additional unique health states may be required to expand estimated impacts. This was particularly apparent with respect to mastitis, lameness, calving trauma, and musculoskeletal injury, all of which could be redefined using gradients of severity or accounting for sequelae.

Conclusions: These disability weight distributions serve as an initial step in the development of the DAL metric. They will be used to assess the time lost due to dynamic phases of dairy cow diseases and injuries. Prioritizing health interventions based on time expands the discussion of animal health to view profits and losses in light of the quality and length of life. The dairy industry needs such a measure to move beyond simply monetizing health issues, i.e. the cost per case, to a more thorough assessment of the implications of time lost due to illness or injury, forced removal, or death.

CH-044-005

Direct economic cost of bovine respiratory disease in US beef calves prior to weaning

Min Wang ¹Liesel Schneider ¹Kathleen Barton ¹David Smith ^{1,*}

¹Pathobiology and Population Medicine, Mississippi State University, Mississippi State, MS, United States

Objectives: Bovine respiratory disease (BRD) is a leading cause of sickness and death in pre-weaned beef calves. The economic loss due to BRD in feedlot cattle has been reported, but similar information for beef calves prior to weaning is not available. The objective was to estimate the direct economic cost of BRD in beef calves prior to weaning.

Materials and Methods: Data were obtained from USDA reports (NAHMS 2007-2008, NASS 2014, and AMS 2014), peer-reviewed papers, Health records (9,921 calves from 28 cattle management groups within 7 Nebraska, USA beef cattle ranches with BRD), and internet based pharmacies. A stochastic simulation model was conducted using computer spreadsheet add-on software. The model was comprised of three parts, cost of BRD mortality, cost to treat BRD, and losses associated with decreased weaning weight from BRD based on the beef cow inventory in 2014. The input variables included percentage of beef cows that calved, percentage of calves born alive, percentage of calves born alive but died before weaning, percentage of deaths at any pre-weaning age due to BRD, weaning weight of calves, 2014 market price of calves weighing, BRD incidence rate, weight lost due to BRD, and cost to treat a calf for BRD, including estimates for antibiotic costs. Cost for labor to treat sick calves and the costs of diagnostic testing were not included.

Results: The results showed the estimate of the total direct economic

cost of BRD in pre-weaned beef calves for 2014 was \$200.3 million (90% CrI 167.6-236.4), of which the total death losses, medical treatment cost and weight loss cost were \$167.0 million (90% CrI 135.4-201.9), \$10.8 million (90% CrI 3.6-17.8), and \$22.5 million (90% CrI 15.9-30.0), respectively. Costs associated with death due to BRD in calves <3 weeks and ≥3 weeks of age were \$56.7 million (90% CrI 41.0-75.3) and \$110.3 million (90% CrI 82.7-142.0), respectively.

Conclusions: We estimate that BRD in pre-weaned beef calves most likely cost US cattle farmers \$200.3 million in 2014. Of this, the largest component (55%) was death in calves ≥3 weeks of age. Therefore, to most effectively minimize the cost of BRD in pre-weaned beef calves, disease prevention and treatment strategies are needed that decrease BRD deaths.

Iodine Concentration in tears, milk and serum after Kelp Supplementation

Ulrike Sorge¹Brian Crooker²Ayhan Bastan³Michala Henriksen⁴

¹Veterinary Population Medicine, College of Veterinary Medicine, University of Minnesota, ²Animal Science, University of Minnesota, St. Paul, United States, ³Ankara University Faculty of Veterinary Medicine, Ankara, Turkey, ⁴Veterinary Clinical Sciences, University of Minnesota, St. Paul, United States

Objectives: Anecdotal reports claim that supplementation with kelp (*Ascophyllum nodosum*) can decrease incidence of pink eye and improve udder health due to increased serum, milk and tear iodine concentrations. Therefore, the objectives of this study were: 1) To measure the increase in iodine in tears, milk and serum of cows after being fed kelp for 30 days, 2) Compare the trace mineral and thyroid status of cows before (d0) and after being fed kelp for 30 days, and 3) To compare the growth rate of bacteria in tears (*Moraxella bovis*) and milk (*St. aureus*, *E. coli*, *St.uberis*) of cows fed no kelp (d0) or kelp (d30) in vitro.

Materials and Methods: Three healthy midlactation Holstein cows per group were either supplemented with 56g of kelp per day or not for 30 days. At day 0, 7, 14, 21, and 30 blood, aseptic milk and tear samples were collected. The samples were analyzed for iodine content. Furthermore, liver biopsies were collected on day 0 and d 30 for mineral analysis and blood samples were additionally analyzed for thyroid hormones. An inhibition test used milk and tear soaked plates from kelp fed cows (d0 and d30) as well as 1% and 7% iodine as positive and distilled water as negative control. Changes in assessed parameters within a group were assessed with sign tests to account for the dependence of the data, while comparisons of parameters between groups were conducted with Mann-Whitney U tests. The significance level was set at alpha=0.05.

Results: Unexpectedly the baseline iodine concentrations of the serum and milk of enrolled cows were higher than anticipated. Nevertheless, the kelp supplementation did increase iodine concentrations in milk and serum of cows and the serum iodine concentrations were positively correlated with milk and tear iodine concentrations. The liver mineral content did not change after kelp supplementation and also the thyroid hormone concentrations remained within the reference range. While the 1% and 7% iodine concentration inhibited the growth of assessed bacteria, none of the milk and tear samples or the distilled water showed any inhibition zones.

Conclusions: As anticipated the feed supplementation with kelp did impact the serum iodine concentration of cattle and milk, tear and serum iodine concentrations were correlated. However, the increased iodine concentration in tears did not inhibit bacterial growth in vitro. Therefore, an increased tear iodine concentration by itself is unlikely to decrease pink eye incidence.

Saint-Hyacinthe, ³Valacta, Saint-Anne-De-Bellevue, Canada, ⁴Rodale Institute, Kutztown, United States, ⁵Agriculture Agri-Food Canada, Sherbrooke Research and Development Centre, Sherbrooke, Canada

Objectives: The objective of this review was to identify non-antimicrobial therapies (i.e. treatments other than antibiotics) for the treatment of clinical mastitis in lactating dairy cows that have demonstrated efficacy in clinical trials, observational studies or experimental studies on mastitis models.

Materials and Methods: A systematic review was performed with eligible studies selected from CAB Abstract, Pubmed and Web of Science from January 1970 to June 2014. Publications in English or French were subsequently screened independently by 3 different reviewers for inclusion and exclusion criteria. References of each included publication were also reviewed. A total of 2,451 manuscripts were first identified after duplicate exclusion. Among the 167 papers remaining after title and/or abstract exclusion, 132 were excluded after full-text assessment to reach 35 included manuscripts. Four additional studies were included after review of the references of included manuscripts. Finally, 39 manuscripts corresponding to 41 studies were included for qualitative synthesis. Assessment of risk of bias in included studies was evaluated using the Cochrane Collaboration's tool for assessing risk of bias. Outcomes evaluated for the evaluation of treatment efficacy were resolution and recurrence of clinical signs which include systematic as well as local signs, bacteriological cure, and, finally, milk production.

Results: Among the 41 included studies, 22 were clinical trials, 18 were experimental studies (15 endotoxin-induced mastitis and three bacterial-induced mastitis), and one was an observational study. The different non-antibiotic treatments evaluated were: conventional anti-inflammatory drugs (non-steroidal and steroidal, n=14), oxytocin with or without frequent milk out (n=5), homeopathy (n=5), phytotherapeutic products (n=4), immunoglobulins based products (n=4), products used to enhance the immune system (n=3), products with bactericidal or bacteriostatic properties (n=2) and probiotic (n=2). High risk of biases was noted in most included manuscripts, with most frequent biases being blinding of participants and personnel (41% of studies), blinding of outcome assessment (38%), and selective reporting (33% of studies). Various other uncategorizable biases were also noted in 92% of the papers. Study power was also a frequent limitation and could have led to type 1 error in studies where only a positive control group was used.

Based on the studies available, homeopathic treatments of clinical mastitis should be considered ineffective. Some phytotherapeutic products or immunoglobulins based products need further investigation before conclusion on their efficacy. Efficacy of oxytocin with or without frequent milking out is inconsistent and some detrimental effects were even reported. Anti-inflammatory drugs have demonstrated potential beneficial effects in experimental models mainly on control of clinical signs (e.g. hyperthermia, depression) associated with clinical mastitis.

Conclusions: To date, no alternative therapies had consistently demonstrated efficacy for the treatment of clinical mastitis based on the resolution of clinical signs, bacteriological cure or milk production in clinical trials. Positive effects of anti-inflammatory drugs have to be confirmed in randomized clinical trials. Finally, to minimize bias, following the CONSORT statement recommendations when reporting clinical trials is strongly encouraged.

Is the current use of homeopathy in agricultural practice target-oriented? - Studies from dairy farms in Germany, France and Spain -

Diana Keller ^{1,*}, Isabel Blanco-Penedo ², Manon de Joybert ³, Albert Sundrum ¹

¹University of Kassel, Witzenhausen, Germany, ²IRTA, Monells, Spain, ³ONIRIS, Nantes, France

Objectives: The success of homeopathic treatment is not only related to the effectiveness of the remedies themselves, but depends also on the appropriateness of farm conditions (e.g. expertise in homeopathic principles, availability of homeopathic experts / remedies, storage of remedies, documentation, etc.). Hitherto there are no studies available providing information about the conditions for the use of homeopathy and the homeopathic procedures on dairy farms. The aim of the survey is to provide an initial overview on the current situation of the use of homeopathy in dairy production.

Materials and Methods: The study was conducted in France, Germany and Spain where homeopathic remedies are frequently used in dairy farm practice. Different questionnaires for farmers and veterinarians were developed by scientists and homeopathic experts (veterinarians) from the International Association for Veterinary Homeopathy (IAVH). In total, 64 farms were visited and served for applying the questionnaires and to gather information about homeopathic treatment procedures on the farms. To ensure the comparability of the data in the three countries, a standard procedure was adhered to, beginning with the stable tour and inspection of stable pharmacy followed by an interview with farmers questioned by the scientist and the homeopathic expert. Every questionnaire was evaluated individually by a scientist and each question assigned to different categories: e.g. prophylaxis, early detection of diseases or lege-artis step of a homeopathic treatment (e.g. anamnesis, selection of remedies, success control). Farmers' level of expertise was assessed by the homeopathic experts by using specific questions about their homeopathic treatment procedure. For the purpose of the evaluation, frequency distribution with or without previous categorisation and a ranking method were used for analysis purpose.

Results: The results of the questionnaires revealed that farm conditions for the use of homeopathy and homeopathic treatment procedure itself were very heterogeneous and differed considerably between farms and countries. The on-farm assessment of the conditions showed inter alia: poor hygiene (33% of all farms used boxes for both diseased and calving animals without implementing some kind of cleaning and disinfection) or non-compliance of specific recommended storage instructions for homeopathic remedies by 40% of all farmers. Early detection measurements such as Body Condition Scoring (14% of farms) or California Mastitis Test (20% of farms never used it) were also rarely or not performed. Most farmers only had a poor level of awareness of the principles of homeopathy (22% of farmers were rated "very poor", 51% "poor" and 27% "moderate"). The use of homeopathy by farmers was often illegal by making use of human products regularly without rededication by a veterinarian (88% of farms) or by use of forbidden substances (Colchicine and/or Aristolochia were found on 11 farms). Moreover, treatments were accompanied by insufficient treatment documentation (52% no, 31% partial, 17% of farms made a complete documentation). The studies revealed that no uniform treatment procedures in the use of homeopathy existed. The results indicate that a homeopathic lege-artis treatment of diseased food-producing animals is missing whereas each farmer seems to have developed his/her own homeopathic treatment strategy without providing evidence with respect to the success of treatment.

Conclusions: The effectiveness of homeopathy cannot be limited to the

efficacy of remedies in a standardised clinical trial. Furthermore, for a target-oriented treatment also appropriate farm conditions have to be implemented. The heterogeneous situation in farm practice makes it nearly impossible to predict the outcome of a homeopathic treatment. The reasons for the heterogeneous use of homeopathy are manifold, but without a monitoring of treatment success on the farm level and the implementation of a homeopathic lege-artis concept, an un-aided use of homeopathy could create unnecessary suffering for diseased animals.

Comments: This project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement n° 311824 (IMPRO).

CM-038-004

Efficacy of homeopathy in livestock concluded from peer-reviewed publications from 1980 to 2014

Caroline Doehring ^{1,*}, Albert Sundrum ¹

¹University of Kassel, Witzenhausen, Germany

Objectives: The use of homeopathy in livestock is widespread and becomes more and more popular in the context of the general aim to reduce the use of antibiotics, especially in food-producing animals. The efficacy of remedies is decisive for its use in diseased animals in respect to animal health and welfare and consumer safety. Therefore, a systematic review of peer-reviewed publications has been conducted to assess the efficacy of homeopathy in cattle, pigs and poultry. The main focus was on studies dealing with homeopathic remedies which could possibly replace antibiotics in the case of infections.

Materials and Methods: The search for scientific publications was performed between February 2014 and June 2014 in multiple databases with search terms defined according to the PICOS approach. Study descriptions were assessed according to various criteria like species, diseases, applied methods, remedies, study design and outcome. Only publications in peer-reviewed scientific journals and doctoral theses were taken into account. The considered studies addressed the efficacy of homeopathic drugs in cattle, pigs or poultry in production diseases under European or comparable conditions. The time frame of publications considered was from year 1980 to 2014. Accessible languages were English and German. The search and filtering process was performed on the basis of the PRISMA guidelines to ensure a transparent and complete reporting and evaluated by the same person. The following information were extracted from each study and further evaluated: author, publication year and source, research body, species, farming system, purpose of application, disease in focus, inclusion and exclusion criteria for experimental animals, diagnostic method and diagnosing person, used remedy, as well as origin, ingredients and potency of the remedy, producer of remedy, way of administration, study design and control groups, methods of measurement and outcome of the study.

Results: 62 publications were identified which met the given criteria (60 individual clinical trials and 4 summarising reports). The publications focussed mainly on cattle (n=40 trials) while only a small proportion dealt with pigs (n=13) and poultry (n=7). 30 studies showed a significantly higher efficacy of the homeopathic remedy in comparison to a control group, whereas 24 showed no medicinal effect and 6 had an inconclusive or not significant outcome. Homeopathic remedies with a low potency were more likely to show a positive effect than highly diluted remedies. Trials performed in a single- or non-blinded randomized-controlled-trial (RCT) or observational trial more likely resulted in a positive outcome

than a double-blinded RCT. Cure rates when comparing treatments with conventional remedies, homeopathy or placebo showed a wide range while the nature of the remedies did not seem to make a big difference. Within the considered studies no repetitions were conducted concerning the use of the same remedy administered to the same species with a comparable medical indication or under comparable conditions.

Conclusions: A general potential concerning the efficacy of homeopathy can be seen but no trial has been repeated in a comparable manner. Thus, no reproducibility of the efficacy of a certain remedy has been proven and cannot be claimed without providing evidence within the specific farm conditions. It cannot be recommended to use homeopathy in order to replace or reduce antibiotics unless evidence of efficacy is reproduced by RCTs under modified conditions. Otherwise, use of homeopathy risks being blamed for increasing health and welfare problems instead of reducing them.

Comments: This project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement n° 311824 (IMPRO).

CM-038-005

In vitro activity of crude extract of Mexican lemon (*Citrus aurantifolia*) on *Staphylococcus aureus* isolated from Small holder dairy herds

Velazquez-Ordoñez Valente^{1,*}, Maria Andrea Ramirez-Mendiola¹, Maria Uxua Alonso-Fresan¹, Benjamin Valladares-Carramza¹, Abdel Fattah Zeidan Mohammed Salem¹, Carlos Bedolla-Cedeño¹, Hugo Castañeda-Vázquez¹, Jorge Luis Ruiz Rojas¹ and Red de Cuerpos Academicos en Salud Animal e Inocuidad Alimentaria

¹Universidad Autonoma Del Estado De Mexico, Toluca, Mexico

Objectives: Oxacillin / methicillin resistant (ORSA / MRSA) *Staphylococcus aureus* has been identified in family production dairy herds which is considered as a public health risk, because of the increasing resistance to antimicrobials, therefore raising the need to seek for new alternatives in the treatment and prevention of mastitis caused by this pathogen in dairy cows. The objective of this study was to evaluate the in vitro activity of crude extracts of Mexican lemon peel (*Citrus aurantifolia*) against *S. aureus* strains isolated from dairy cows with subclinical mastitis in smallholder dairy herds.

Materials and Methods: Ninety four *S. aureus* strains were isolated from small dairy herds to study in vitro sensitivity tests to Lemon crude extracts using lemon peels on a 20% weight/volume dry matter basis using distilled water and ethanol as solvents. 1/10 serial dilutions were used to evaluate the in vitro antimicrobial activity on *S. aureus* (0.5 MacFarland). In vitro test was run by diffusion method in Mueller Hinton agar; 10 µl dilutions (25ug/mL w/v) were run by impregnated unidiscs with crude extract, the plates were incubated at 37 ° C for 24h. The inhibition zone was measured and expressed in mm according to the inhibition diameter zone which was analyzed by one way ANOVA test (P<0.05). Control tests were run using 1µg oxacillin unidiscs against sensible and resistant *S. aureus* strains. *S. aureus* ATCC 43300 was the positive MRSA control strain used to test the crude extract.

Results: The results of the activity of the extract of *C. aurantifolia* showed antimicrobial activity against *S. aureus* isolates with inhibition zones of 2 to 5 mm when compared to *S. aureus* ATCC 43300 as the control strain. All the isolations showed different in vitro sensibility to

the crude extract (p<0.05), when using 1/10 and 1/20 extract dilutions, showing its antimicrobial in vitro effect in comparison to oxacillin unidiscs. *C. aurantifolia* crude extract 1/20 dilution showed reduced in vitro antimicrobial effect over *S. aureus* isolations and control strains when compared to 1/10 dilution.

Conclusions: The results suggest a potential antimicrobial activity of the extract of *C. aurantifolia* which could have a potential application in clinical research to evaluate phyto compounds and their antimicrobial effect on *S. aureus* in dairy cattle.

Comments: The results pose a positive expectation for the isolation of new phytocompounds with antimicrobial activity when used as teat dip disinfectants or antimicrobial drugs in dairy cows.

DH-024-001

Predicting periparturient diseases based on prepartum dry cow behaviourAnouar Belaid ¹Maria Rodriguez-Prado ¹Sergio Calsamiglia ^{1,*}¹Servei de Nutricio i Benestar Animal, Univeritat Autònoma de Barcelona, Bellaterra-08193, Spain

Objectives: The transition period in dairy cows is associated with a peak incidence of diseases (hypocalcemia, ketosis, retained placenta, displaced abomasum, metritis and mastitis). These diseases have a negative impact on the economy of farms. Preventive treatments (anionic salts, calcium boluses, monensin, dietary additives,...) to the dry group are often successful but expensive. The objective of this trial was to test a new pedometer system to assess if the prepartum behavior is a good indicator of the risk of periparturient diseases in dairy cows to allow for directed animal-specific preventive treatments.

Materials and Methods: A new pedometer system (Track a))) cow, ENGS System innovative dairy solutions, Israel) that monitors cow steps, lying and the standing time, swaps from laying to standing, and access to the feedbunk (number of times and time per access) was used in a commercial farm with 1,200 dairy cows in Lleida (Spain). Dry cows were located in a compost-bedded barn with more than 30 m²/cow and provided with a pedometer at least 21 days prior to calving. Behavior data from a total of 129 calvings were recorded and the incidence of postpartum pathologies recorded. The normal behavior of dry cows, and the association between prepartum behavior and specific diseases was explored. Data analysis was performed with SAS software (version 9.1).

Results: On average, dry cows spent 8.4 h standing, 12.3 h laying, changed positions from laying to standing 12.1 times/day, and did 1913 steps. They attended to the feedbunk 9.4 times and spent a total of 3.3 h (average of 21 minutes each access time). When cows were sick in the postpartum (for any disease), there was a reduction in the number of visits to the feedbunk (9.4 vs 8.0 times), in the time at the feedbunk (200 vs 129 minutes), in the number of swaps from laying to standing (12.1 vs 10.1) and in the number of steps (1913 vs 1386); and an increase in the laying time (735 vs 840 minutes). The pattern of changes in these indicators were unique and specific for each disease. Cows with DA walked less and reduced the number of visits to the feedbunk, and increased the laying time. Cows with metritis reduced the number of visits and the time in the feedbunk, reduced the number of steps and increased the standing time. Cows with hypocalcemia reduced the number of visits and time spent in the feedbunk, reduced total steps and reduced the number of swaps from laying to standing, and increased the standing time. Cows with retained placenta reduced the time at the feedbunk and increased the standing time. Cows with mastitis increased laying time. All these changes in behaviour were observed at least 21 days before calving, providing ample time for taking preventive actions.

Conclusions: A new generation of pedometers can be successfully used to identify changes in dry cow behavior that are associated with an increased risk of specific periparturient diseases, which may help in the application of animal-specific preventive treatments

DH-024-002

What really matters in herd health advice? The use of in-depth, qualitative interviews to investigate the efficacy of current advisory strategies.Alison Scrase ^{1,*}David Main ¹Anne Haase ²Helen R. Why ¹Emma Roe³Kristen Reyher ¹¹School of Veterinary Sciences, ²School for Policy Studies, The University of Bristol, Bristol, ³Geography and Environment, University of Southampton, Southampton, United Kingdom

Objectives: Herd health planning is a critical component of modern dairy farming, yet recent data (Bell et al. 2006) suggests negative views on this process are common and implementation of recommendations is often poor. What, then, really matters in this process, and how can it be enhanced? To ensure 'agreement and common purpose' (Sibley 2006), an in-depth understanding of both veterinarian and farmer perceptions is critical. This study is a qualitative approach to understanding this context, with the objective of revealing critical insight into what is the nature of, and what influences, veterinary advice and communication with farmers on herd health.

Materials and Methods: Farmers (n=14) located in the South West of England and their respective vets (n=10) from six South West practices were recruited via a UK retailer. Each farm was visited during a routine fertility consultation, and conversations between veterinarians and farmers were audio recorded. After completing the consultation, farmers and veterinarians were interviewed in an in-depth, semi-structured format to investigate perceptions and impacts of positive/negative communication, perceptions of veterinarian and other advisory roles on farm and attitudes towards motivation and compliance to advisory recommendations, particularly those relating to lameness and mastitis (mean interview duration 53.7 minutes).

Interview data was transcribed and organised/analysed thematically using the template methodology described by King (2004), to allow the comparison of farmer and veterinarian perspectives within this context. A sample size of 24 interviews was expected to provide sufficient variation to reach data saturation in thematic analysis, in the context of similar qualitative work in this field (Horseman et al. 2014).

Results: Preliminary data suggest that advisory behaviours on-farm, both from the veterinarian (giving advice) and farmer (seeking/receiving/ implementing advice) are influenced by factors such as the farm complexity (history, structure, workers, priorities, capabilities), knowledge and experience of both parties, the role of external advisors, and the professional and personal relationship established between veterinarian and farmer. These factors are in turn underpinned by a host of values and attitudes, such as those relating to disease processes, implementing change, the dairy cow and the veterinary role.

Conclusions: The efficacy of a herd health plan rests not only in the recommendations themselves, but in engaging farmers in plan delivery. Interview data suggest that reaching 'agreement and common purpose' is a complex phenomenon that emerges through the interaction of many personal and practical factors, not merely the content of the programme delivered. Consideration of these results (in full detail) could therefore offer those working in advisory contexts the opportunity to enhance their delivery of herd health plans and increase the potential for successful implementation of advice on farm.

DH-024-003

"KOers": A novel online data collection tool to support transition cow managementG Hofste ¹E Nijenhuis ¹M van den Berg ¹S Boersema ¹T Westerhout ¹J de Boer ¹J Lievaart ^{1,2,*}¹Dairy Consultancy, Cowcept, Loppersum, Netherlands, ²School of

Animal and Veterinary Sciences, Charles Sturt University, Wagga Wagga NSW, Australia

Objectives: Programs to support data collection in transition cow management are widely discussed over the last decade. Pitfalls of most current programs are; bias in data collection, how to engage farmers, inflexible systems and how to underpin day to day management.

To overcome these issues, we developed a program called "KOers" which records online various data on transition cows via fixed protocols. Our first objective was to improve data collection for early detection and intervention in transition cow management. The second objective is to add value to the regular herd health visits performed by dairy practitioners.

Materials and Methods: The software is written in a way that the farmer can choose between various components to be included (eg. udder health, lameness, reproduction, ketosis), and which parameter(s) per component have to be recorded and at which frequency. Data can be collected either by farmers and their coworkers or by veterinarians directly online via an I-pad. At the initial phase the program has been implemented on 13 Dutch dairy farms for 18 months (2014-2015) at a large dairy practice in the Northern part of the Netherlands. All farmers participated in a weekly schedule and all components of udder health, lameness, reproduction and ketosis were included. Data were collected by three practitioners. To assess the results of the program, herd health parameters before and after 12 months after the program KOers had been implemented were analyzed.

Results: The average herd size of the 13 farms was 123 vs. 119 cows at the start and the end. The Daily Dosage (DD) of antibiotics use per cow per year did decrease from 4.3 to 2.2 on average. The average Bulk Somatic Cell Count (BMSCC) did not change (155* 103 vs. 152*103). The number of cases of clinical mastitis was on average 14.1% at the start and 12.5% after the tool was implemented for 1 year. Lameness cases did decrease from 20.1% to 12.6%. The inter-calving period decreased from 418 days to 403 days on average including a decreased number of inseminations per cow (2.2 vs. 1.9).

Conclusions: From our own and the farmers experience with the KOers system, we believe it's a valuable additional tool to successfully monitor the transition cow period and add value to the regular herd health visit of dairy practitioners. The objectives have been met and the program will be enrolled on a large scale on Dutch dairy farms.

DH-024-004

Use of Acute Phase Proteins for Monitoring Cow Health and Productivity in Dairy Cattle in the UK

Alastair Macrae ^{1,*}, Eilidh McCulloch ², Elizabeth Burrough ¹, Julie Forrest ¹, Darren Shaw ³, David Eckersall ²

¹Dairy Herd Health and Productivity Service, RDSVS, University of Edinburgh, Midlothian, ²School of Veterinary Medicine, University of Glasgow, Glasgow, ³RDSVS, University of Edinburgh, Midlothian, United Kingdom

Objectives: Analysis of blood biochemistry (e.g. metabolic profiles) is used as a method for the routine evaluation of nutritional adequacy in dairy herds with the purpose of identifying production-limiting factors. However subclinical disease may also be present within the herd, and may confound the interpretation of metabolic profile analysis. The aim

of the present study was to 1) evaluate the diagnostic value of using Acute Phase Protein (APP) assays in metabolic profile screening programmes and 2) examine the association of APP with clinical disease and production parameters in dairy cows.

Materials and Methods: Blood samples were obtained from 12 commercial dairy herds as part of a routine nutritional monitoring programme using metabolic profiles. Aliquots of serum were frozen and stored at -20°C, and subsequently analysed for the APP haptoglobin (Hp) and Serum Amyloid A (SAA) using a haemoglobin binding method and an ELISA respectively.

Individual cow somatic cell count (ICSCC) data was obtained for the two milk recordings closest to the actual date of blood sampling from 9 farms. Appropriate disease records were obtained from 9 farms, and any disease occurrences within 100 days of the blood sampling date were recorded along with the date they occurred. Relevant fertility data recorded from all 12 farms included date of 1st service, number of services, and date of successful service and whether the cow was back in calf by the end of that lactation. Three farms were organic.

Data was analysed using mixed effect models with farm identity entered as a random effect to account for intra-farm correlation, and system (standard or organic), lactation number (primiparous or multiparous) and group (EARLY, MID or DRY) added as fixed effects. Data was analysed either as raw data, or binomial data (using values above or below SAA and Hp thresholds) where Relative Risk was calculated with 95% CI.

Results: A total of 388 blood samples were received from individual cows from the twelve farms. Using a threshold of 0.02 g/l, 155 cows (40%) had elevated Hp results. Using a threshold of 24 mg/l, 165 cows (42.5 %) had elevated SAA results. Hp and SAA were significantly positively correlated ($r_s=0.377$, $P<0.001$), although only 64.5% of the samples were in agreement (ie. SAA and Hp were either both high or both low relative to thresholds).

There were 75 disease events recorded in the cows sampled, with 39 separate cases of mastitis, 15 cases of metritis or endometritis and 10 cases of lameness. There was no significant association between elevated APP and all disease occurrences. However the Relative Risk of a cow having a lameness event if she had a high SAA result was 6.203 (95% CI: 1.363 – 28.24). Using either the actual ICSCC value or a 200,000 cells/ml threshold, there was no significant association between APP (either Hp or SAA) and ICSCC.

There was no significant effect of elevated APP (either Hp or SAA) on production, measured by total lactation yield, 305 day lactation yield or milk per day of lactation. The Relative Risk of a cow being culled if she had a high Hp result was 1.506 (95% CI: 1.086 – 2.088).

Cows with elevated Hp levels received more services ($P=0.038$), took an average of 21.5 days (± 9.62 SEM) longer to get in calf ($P=0.025$), and had a 100 day in-calf rate of 20.8% compared to those cows with low Hp levels (33.2%) ($P=0.007$). The Relative Risk of a cow being in calf at 100 days in milk if she had an elevated Hp value was 0.616 (95% CI: 0.432 – 0.878).

Conclusions: This study of 388 cows from 12 different dairy farms showed that a significant proportion of cows had elevated Hp and SAA levels (over 40%). There was a significant positive association between SAA and lameness occurrence. The main findings showed a significant association between elevated Hp levels and an increased risk of culling and reduced fertility parameters, which illustrate the potentially harmful effects of inflammation and subclinical disease on dairy cow productivity. Inclusion of APP analyses may provide a useful additional tool for the monitoring of dairy cow health and welfare.

DH-024-005

On farm cattle mortality and related risk factors in Estonian dairy herds

Kaari Reimus¹ Toomas Orro¹ Arvo Viltrop¹ Kerli Mõtus¹¹Estonian University of Life Sciences, Tartu, Estonia

Objectives: Increasing dairy cow mortality has been reported in several countries all over the world. Mortality of dairy cattle causes financial loss for the farmer and is connected to animal welfare. The aim of this study was to determine the mortality risk and rate, as well as risk factors for on-farm mortality (unassisted death and euthanasia) in cattle of Estonian dairy herds in years 2013 and 2014.

Materials and Methods: Data was collected from Estonian Agricultural Registers and Information Board. Mortality risk and rate in years 2013 and 2014 was estimated based on data consisting cattle from all dairy herds (more than 75% of dairy breed cows within herd) in Estonia, including 274,327 animals from 2,631 farms, and 283,545 animals from 2,321 farms for 2013 and 2014, respectively. Two years study period was used for screening multivariable associations between potential risk factors and mortality including animals present in dairy herds at the start of the observation period (1st of January 2013) and animals born during years 2013 and 2014. The dataset included 362,683 animals from 2,614 farms. All statistical analyses were performed using STATA MP version 14 (StataCorp LP, College Station, USA). Factors of interest were age group, breed, gender, herd size and region. Multivariable Weibull proportional hazard models with farm as random effect were composed for detecting significant associations between potential risk factors and on-farm mortality.

Results: In 2013 there were 12,834 deaths and euthanasias, number of animal-years was 209,474, mortality risk 4.68% and mortality rate 6.13 per 100 animal-years. In 2014 13,854 deaths and euthanasias occurred resulting mortality risk of 4.89% and mortality rate 6.37, number of animal-years in the analysis was 217,527. The increase of cattle mortality in dairy herds in 2014 compared to 2013 was statistically significant ($p < 0.05$). Statistically significant interactions were found between age and gender, breed and gender as well as between herd size and region. The hazard of on-farm mortality differed significant between gender and age groups ($p < 0.001$), being highest among females aged <12 months (baseline group with HR = 1), followed by males in the same age group (HR = 0.87, 95% CI 0.72; 1.06, $p = 0.166$). Consistent with all age groups males had lower hazard of dying compared to females. The hazard of failure was significantly lower among female animals from Estonian Red breed (HR = 0.80, 95% CI 0.76; 0.85, $p < 0.001$) and category of 'other' breeds (HR = 0.69, 95% CI 0.59, 0.81) compared to female Estonian Holsteins (baseline group). The risk of on-farm death and euthanasia among male Estonian Holstein and male Estonian Red cattle did not differ significantly from the baseline group. The hazard of mortality was highest among herds with 100-300 cows located in North of Estonia (HR = 2.00, 95% CI 1.72; 2.31, $p < 0.001$) and in herds with 300-600 cows in South of Estonia (HR = 1.87, 95% CI 1.67; 2.08, $p < 0.001$) compared to smallest farms (<100 cows) positioned in South.

Conclusions: This is the first study demonstrating the mortality rate in Estonian dairy cattle population. On-farm mortality has increased between years 2013 and 2014. There are considerable differences between age, breed and gender differences contributing to mortality risk. The effect of herd size on cattle mortality was influenced by the region. This study is a good starting point for more detailed research that could identify significant factors associated with cattle mortality that could be used to improve animal welfare and farmer's profitability.

DI-029-001

Calf umbilical disorders : evaluating correspondence between ultrasound images, abdominal palpation and subsequent surgical observations.

Renaud Maillard ^{1,*}, Mariam Nouvel ¹, Manon Kammacher ¹, Guillemette Bataille ², Enrico Martinelli ¹

¹Pathologie Des Ruminants, École Nationale Vétérinaire De Toulouse (Envt), Toulouse, ²École Nationale Vétérinaire D'alfort, Maisons-Alfort, France

Objectives: Calf umbilical disorders cause complications and important economic loss. An accurate diagnosis is mandatory to make an adequate prognosis and good therapeutic choices. In this study, we evaluate the efficiency and the interest of this tool in omphalophlebitis diagnosis when compared to abdominal palpation and subsequent surgical observation.

Materials and Methods: 37 calves were referred at the farm animals hospital of the Toulouse vet school (ENVT) for a clinical suspicion of omphalophlebitis in 2015. All of them were carefully examined at arrival. Physical examination included abdominal palpation. Physical examination was followed by ultrasonography of the abdomen, using a 1-8 Mhz sectorial probe. Subsequent surgery was performed in all cases, leading or not to a confirmed diagnosis of omphalophlebitis. 28 calves presented really omphalophlebitis (the more frequent cause of error was hernia, followed by abscesses outside of the navel).

Results: Palpation is of great use when calves are younger than 2 weeks old. Palpation is of no use when the calves are older than 3 months old.

In case of infection of the umbilical vein, ultrasonography enables : Se = 1, Sp = 1, PPV = 1, NPV = 1 ; in case of posterior disorder (urachal or umbilical arteries) : Se = 0.86, Sp = 1, PPV = 1, NPV = 0.85.

Moreover, even if the abdominal palpation permits an accurate diagnosis, ultrasonography provides useful information (nature of the vessels involved, size of the lesions, signs of peritonitis, involvement and lesion of the urine bladder...).

Conclusions: Ultrasonography is more and more used by veterinary practitioners. Trained vets can perform easily and promptly ultrasonography in calves suffering from omphalophlebitis. The performances of ultrasonography in this field of medicine are quite good, superior to the physical examination alone. Because ultrasonography allows the detection of unrevealed lesions useful to know before surgery, this imaging technique could be more and more used in the field.

DI-029-002

Comparison of ultrasonographic findings obtained using 5 MHZ linear and microarray scanners in cattle with lung and pleural pathology.

Phil Scott ^{1,*}

¹Capital Veterinary Services, Haddington, United Kingdom

Objectives: Modern portable ultrasound machines provide the veterinary practitioner with an inexpensive, non-invasive tool with which to examine the pleural surfaces and superficial lung parenchyma of cattle with suspected respiratory disease however published studies have used 5MHz microarray scanners when most veterinary practitioners use 5MHz linear scanners everyday for trans-rectal early pregnancy diagnosis. The

objective of this prospective study was to determine whether a 5MHz linear scanner significantly altered the diagnosis and prognosis of lung and pleural pathologies

Materials and Methods: Few veterinary practitioners routinely examine the lungs and pleurae of cattle with suspected respiratory disease. Ultrasonographic examination of cattle with suspected respiratory disease was undertaken over a three year period using both 5MHz linear and microarray scanners with results recorded as mp4 files on computer using Elgato software. Cases that did not respond to treatment were euthanased for welfare reasons and necropsied. Follow-up of cases was undertaken after three months by telephone.

Results: Growing cattle (6) and adult cattle (16) with chronic suppurative pneumonia gave similar results with respect to the dorsal margin of lung pathology and ultrasonographic appearance of lung pathology; no ultrasonographic abnormalities were observed in a similar number of healthy control cattle using either scanner head. Lobular lung pathology was observed dorsally in four cows with chronic suppurative pneumonia represented by numerous hypoechoic columns extending 2 to 6 cm into the lung parenchyma. This sonographic appearance abruptly changed as the probe was moved ventrally to large hypoechoic areas corresponding to lung consolidation with the echogenic appearance of liver (hepatoid change). This abrupt change from normal lung to consolidation was observed in all other cases. The dorsal margin of a pleural effusion in one cow was readily identified using both scanners as an anechoic area which increased in depth to 16 cm as the microarray probe head was moved ventrally but measurement of the effusion with the linear scanner was only 6-7 cm due to the limited field depth. Similarly, a pleural abscess extended to 15 cm from the chest wall (microarray probe) but a maximum depth of 6-7 cm was recorded using the linear probe.

Conclusions: 5MHz linear probes can be successfully used to identify lung pathology such as chronic suppurative pneumonia and measure its dorsal margin which is the critical factor in prognosis of this disease process. The depth of pleural effusion cannot be measured beyond the 9-10 cm range of a linear probe (less 2-3 cm of chest wall) but can be estimated by how far dorsally it extends. While the area of pleural surface affected by an abscess can be determined, its depth beyond 6-7 cm cannot be measured. In this study the limited depth of a linear probe did not affect the diagnosis nor prognosis of the diseases reported.

DI-029-003

Prevalence of lung lesions using thoracic ultrasonography in pre-weaned calves from dairy herds in Québec, Canada.

Sébastien Buczinski ^{1,*}, Marie-Eve Borris ¹, Jocelyn Dubuc ¹

¹University of Montréal, St-Hyacinthe, Canada

Objectives: Thoracic ultrasonography and observation of lung ultrasonographic consolidation has been recently developed as a fast and non-invasive way to assess bronchopneumonia associated lung lesions. The objective of this cross-sectional study was to assess the prevalence of lung consolidation in pre-weaned calves in dairy herds.

Materials and Methods: Thirty nine dairy herds were randomly selected in the client list of the ambulatory clinic of the Université de Montréal to participate to this cross-sectional study conducted during the summer 2015. A questionnaire focusing on calf feeding and raising practices was completed with the producer at the day of the visit. Each

calf (min 6 calves, max 12) was assessed using a complete thoracic ultrasound examination (7.5 MHz linear probe, I-scan, Draminski, PL) focusing on the maximal depth of consolidation observed. Two different cut-offs for identifying a calf with consolidation were selected. A high sensitive definition of consolidation was to have at least one site with a consolidation depth ≥ 1 cm (Cons1). A more specific definition was used defining a consolidated calf when at least one site with a consolidation depth ≥ 3 cm was found (Cons3). Descriptive statistics were calculated.

Results: A total of 318 pre-weaned calves from 39 different herds were enrolled in this study. The median number of lactating cows in these herds was 80 (ranged from 55 to 280). The maximal quantity of milk replacer volume offered to calves during the pre-weaning period varied from 4 to 16L per day (median=8L). The herd-level prevalence of Cons1 varied from 0 to 80.0 % (median 16.7%; 25th percentile 10.4%; 75th percentile 41.2%; 90th percentile 60.0 %). The herd-level prevalence of Cons3 varied from 0 to 70% (median 8.3%; 25th percentile 0%; 75th percentile 20.8 %; 90th percentile 33.3%).

Conclusions: Despite the fact that this study was performed in a period with a relatively low anticipated incidence of enzootic pneumonia (ie. Summer time), ultrasonographic evidences of lung lesions were commonly found in dairy herds. Interestingly, the prevalence of these lesions was highly variable between herds.

DI-029-004

Interest of ultrasonography for the diagnostic of congenital heart defects in cattle: 12 years of experience 2003-2015

Nora Cesbron ¹, *Raphaël Guatteo¹ Sébastien Assié¹ Christophe Chartier¹ Alain Douart¹

¹Oniris, ⁴⁴³⁰⁷Nantes Cedex 0³, France, France

Objectives: In routine cattle practice, heart congenital defects are never the reason spontaneously expressed by the farmer to call his vet. Heart congenital defects account for 3% of the whole congenital defects in cattle. Among heart congenital defects, abattoir surveys and/or description from veterinary hospital case reports reported that ventricular septal defect (VSD) is the most frequent (42-65%). The aim of this presentation is to describe the clinical, ultrasonography and necropsy findings of the cases of heart congenital defects found during a 12 years period in the Clinics for Ruminants of Oniris.

Materials and Methods: During this period, clinical, ultrasonography and necropsy data were available for 100 cases.

The ultrasonographic examinations were made while the animals were standing using a 2.5 MHz phased array transducer (Mylab Five Vet, HospiMedi France) in 2-D Mode. The heart was ultrasonographically examined on the right cranial parasternal side in six positions as classically described in small animals. VSD were easily and systematically observed. The distinction between other malformations, Patent Ductus Arteriosus (PDA), Aortic Stenosis or complex congenital cardiac defect like Tetra/Pentalogy of Fallot, was not always easy to make especially regarding the identification of all defects.

Results: The clinical observations led to the following patterns:

- Clinical suspicion based on clinical signs only related to cardiovascular system in 25 cases
- Clinical suspicion associated with growth retardation in 20 cases
- Clinical suspicion associated with chronic respiratory disorders for

which antibiotics and/or NSAIDs were ineffective in 20 cases

- Clinical suspicion associated with multiple malformations (head, eyes, bones) in 20 cases.
- Clinical suspicion and/or endocarditis in 15 cases.

At necropsy:

- Ventricular Septal Defect (VSD) was noticed in 86 cases
- Atrial Septal Defect (ASD) was noticed in 22 cases
- Tetra and Pentalogy of Fallot in 9 cases
- Other malformations (Patent Ductus Arteriosus, Aortic Stenosis,...) in other cases
- Endocarditis associated with VSD, in 15 cases, only in animals older than 2 years.

Conclusions: Our results confirm that VSD is the most frequent heart congenital defects in cattle, but less frequently in association with other defects or associated/secondary lesions such as endocarditis. Our results highlight also that heart congenital defects must be suspected in clinical pattern such as growth retardation or chronic respiratory disease. In that specific case, ultrasonography is a sensitive and specific method for both investigating diagnosis and making a prognosis. Ultrasonography could also help to more precisely define phenotypes to investigate putative genomic patterns underlying these defects.

DI-029-005

Ultrasonography of the rumen wall as a potential diagnostic tool to diagnose of Subacute Rumen Acidosis (SARA) in fattening bulls.

Enrico Fiore ¹, *Leonardo Armato¹ Massimo Morgante¹ Sonia Giambelluca¹ Matteo Giancesella¹

¹Department of Animal Medicine, Productions and Health, University of Padua, Legnaro, Italy

Objectives: Importing bulls is a common practice in intensive system of beef cattle in Italy. The acclimation period following the restocking is a critical phase, where animals change from a pasture diet to a high concentrate ration increasing the risk of Acidosis or Sub Acute Ruminant Acidosis (SARA).

Ruminal mucosa thickening in response to volatile fatty acids concentration and rumen pH are well established; rumenitis are a frequent sequel to acidosis.

The aim of this study was to evaluate the viability of transabdominal ultrasonography of the rumen mucosa as a suitable, non-invasive diagnostic tool to identify beef cattle affected by SARA.

Materials and Methods: One hundred– fifty four bulls of Charolaise breed were selected in 2 farms of 2500 feedlot cattle in the North-East, Italy. The animals were imported from France with an average weight of 424.5±33.4 kg and an average age of 17.0±1.9 months.

The arriving beef cattle were placed on a fibrous acclimation diet for 5 days prior to the total mixed ration (TMR) high concentrate growth diet. Stall had a separate feed bunk and watering point. Dry matter intake (DMI) mean values were recorded for all animals during the period of study (DMI: 18±1.5 Kg per animal; DM: 9.78±0.8 per animal).

Individual rumenocentesis were carried out 4-6 h after feeding, 10 days after housing. Rumen fluid was collected using a 13G 105-mm needle and a 50ml syringe from a disinfected area in the left flank, from the

ventral sac of the rumen, approximately 15–20 cm caudal and ventral to the costochondral junction of the last rib. 15 ml of rumen fluid were collected from each animal.

Ruminal pH was measured immediately after sampling using a portable pH meter.

Ultrasonographic examination of the rumen wall was conducted on the same point used for rumenocentesis with an 6.6MHz convex transducer (acoustic windows = 7cm).

One way Analysis of variance was used to detect differences in measured parameters. Regression analysis (R2) and Pearson's correlations were performed with thickness of the rumen wall, rumen mucosa as dependent and ruminal pH as independent variables. Receiver Operating Characteristics Analysis (ROC Analysis) were conducted to identify suitable cut-off for thickness of the rumen mucosa ultrasonography.

Results: The ruminal fluid pH findings of the 154 young bulls showed significant statistically differences ($P < 0.001$): $pH < 5.5$ (29 animals); $5.5 < pH < 5.8$ (35 animals); $pH > 5.9$ (90 animals).

The regression analysis conducted on ruminal fluid pH and total ultrasound thickness of rumen wall and rumen mucosa showed respectively $R^2 = 0.5637$ and $R^2 = 0.5895$.

Pearson's analysis showed good interaction between pH and total ultrasound thickness of rumen wall (-0.700 ; $P < 0.0001$) and rumen mucosa (-0.7921 ; $P < 0.0001$).

Roc analysis revealed that cut-off values for the mucosal thickness of 7.8 mm had sensitivity of 0.85 and specificity of 0.81 to identify animals with a rumen fluid < 5.8 at 4-6 h after feeding.

Conclusions: Our results show that after 10 days from the housing 41.55% of the fattening bulls had a rumen pH lower than the threshold value of 5.8. This lowering of the pH may be attributed to the sudden change in diet and the difficulty that the bulls may have to adapt.

The thickening of the ruminal mucosa is also well correlated with the lowering of ruminal pH.

Transabdominal ultrasonography of the rumen mucosa has the potential to be a suitable diagnostic tool to identify fattening bulls affected by SARA. This study provides encouraging preliminary data warranting further examination and validation in fattening bulls.

Ultrasound findings of common pathologies of the female genital system of small ruminants

Mario Balaro¹, *Ana Lúcia R. S. Maia¹ Ana Clara S. Ribeiro¹ Alex S. Santos¹ Luiz Fernando G. M. Moura¹ Jeferson F. Fonseca² Phillip Scott³ Felipe Z. Brandão¹

¹Clinical and Animal Pathology, Universidade Federal Fluminense, Niterói, ²Embrapa goats and sheep, Coronel Pacheco, Brazil, ³Royal School of Veterinary Studies, University of Edinburgh, Edinburgh, United Kingdom

Objectives: Dysfunctions of the female genital system in small ruminants are common findings in the buiatrics practice. This study reports the prevalence and ultrasound appearance of some common reproductive tract pathologies of small ruminants under tropical conditions in Brazil.

Materials and Methods: A three years' retrospective study of ultrasound data collected during pregnancy diagnosis and evaluation of the

reproductive tract was carried out from September 2012 to September 2015 at Rio de Janeiro State. A total of eight sheep flock and four dairy goat flock raised under extensive and intensive management systems, respectively, were used in the study. A ultrasound device (Sonoscape S6®, Sonoscape, Yizhe Building, Yuquan Road, Shenzhen, China) coupled to a linear transducer of 7.5 MHz (transrectal) or 5 MHz convex (transabdominal). B-mode and Color Doppler-mode ultrasound tapes were recorded and evaluated by the same operator (MB). The chi-square test was adopted for frequency comparison ($P < 0.05$).

Results: Ultrasound data were collected from 1453 examinations (60 per cent ewes and 40.0 per does). Reproductive disorders were detected in 137/1453 (9.5%). Of these, hydrometra was the major occurrence (3.7%; 53/1453), followed by aseptic resorption of the embryo/fetus (2.3%; 33/1453), and recent embryony/fetal death detected by the lack of heartbeat (1.3%; 19/1453). Other findings in descending order were: cystic endometrial hyperplasia (0.6%; 9/1453), follicular cyst (0.6%; 9/1453), septic resorption (0.2%; 3/1453), pyometra (0.1%; 2/1453), hydrosalpinx (0.1%; 2/1453), and single cases of ovarian tumour, macerated fetus, mummified fetus, luteal cyst, cervicitis, retained placenta, and supracervical abscess (0.07%; 1/1453). Sheep had significantly fewer reproductive disorders than goats (5.3%; 46/865 vs. 15.5%; 91/588 $P < 0.05$). In goats, there was a greater occurrence of hydrometra (8.2%; 49/588 - $P < 0.05$) followed by aseptic resorption (2.7%; 16/588). In sheep, the occurrence of aseptic resorption came first (2.0%; 17/865 - $P > 0.05$) followed by recent embryony/fetal death (1.3%; 11/865).

Conclusions: Dairy goats had significantly more reproductive tract disorders than sheep where hydrometra was the major issue. Ultrasonography provides clinically useful information relating to diagnosis, prognosis, and therapeutics.

Comments: The authors have a vast visual material on the subject. So, it is sought the acceptance of the abstract as an oral presentation under the aim to share videos and knowledge with the public at Buiatrics congress and stimulate the discussion about the topic.

DI-029-007

Traumatic reticuloperitonitis : correlation between necropsy and ante mortem clinical and laboratory data (ultrasonography, biochemistry, hematology)

Renaud Maillard¹, *Guillemette Bataille² Manon Kammacher¹ Mariam Nouvel¹ Enrico Martinelli¹

¹Pathologie Des Ruminants, École Nationale Vétérinaire De Toulouse (Envt), Toulouse, ²École Nationale Vétérinaire D'alfort, Maisons-Alfort, France

Objectives: The purpose of this study is to determine the reliability of ultrasonography in traumatic reticuloperitonitis diagnostic (TRP) in cattle admitted at the ENVT farm animals hospital, compared to the results of physical examination, blood biochemistry, hematology.

Materials and Methods: 73 cows were admitted for a clinical suspicion of TRP. Complete physical examination (pain, tachypnea, tachycardia, anemia, milk drop) , ultrasonography of the reticulum using a 3.5-5 Mhz sector probe, blood biochemistry (total proteins, fibrinogen), hematology (white and red blood cell counts) were performed. 38 (on 73) had to be euthanised or died during hospitalisation, allowing an accurate diagnosis at necropsy.

When compared to necropsy, sensitivity (Se), specificity (Sp), Positive

Predictive Value (PPV) and Negative Predictive Value (NPV) were calculated for each ante mortem test.

Results: Physical examination alone is of poor value (Se and PPV < 0.25). Blood cell counts and physical examination are of no use too. These figures are even worse when facing chronic TRP cases (which represent the major part of cases).

Combining physical examination and ultrasonography of the reticulum leads to: Se = 0.81, Sp = 0.47, PPV = 0.65, NPV = 0.67. Combining physical examination, ultrasonography and plasmatic biochemical values leads to: Se = 1, Sp = 0.38, PPV = 0.62, NPV = 1. Ultrasonography is of great value when considering signs of peritonitis, signs of inflammation, aspect of the reticulum wall, motricity.

Conclusions: Traumatic reticuloperitonitis is a common and often severe disease (taking in account the number of cattle concerned and the induced lesions on cattle organs). This leads to productive losses and anticipated culling. That is why it is convenient to set a precise diagnostic in animal husbandry, so that the farmer can take an adequate decision concerning the future of his animal. Outside of the reproductive surveys, ultrasonography in cattle is a technic that has been developed a lot in the last few years. This study assesses the great value of ultrasonography in reticuloperitonitis diagnosis.

EDU-022-001

Developing a Producer-Centered Approach to Design and Optimize Training Programs in Antimicrobial Stewardship

Chelsey Ramirez^{1,2,*}, Brian Aldridge^{1,2}, Dennis French^{1,2}, Lawrence Firkins³, James Lowe^{1,2}

¹Department of Veterinary Clinical Medicine, ²Integrated Food Animal Medicine Systems, ³Department of Veterinary Pathobiology, University of Illinois at Urbana-Champaign, Urbana, United States

Objectives: While there have been many studies exploring the impact and effectiveness of antimicrobial stewardship programs in people, there is little data to define the components of similar initiatives in livestock production. Effective teaching encompasses complex tasks that include the planning, preparation and delivery of learning activities, in line with the expectations and needs of the learners. The objective of this study was to collect data regarding antimicrobial use, behavior and attitudes, along with information related to learning preferences of producers in Illinois with the aim of developing educational materials and delivery platforms.

Materials and Methods: Areas of strengths and weaknesses in knowledge, attitude, behavior, and practice in antimicrobial usage were identified by interviewing twenty dairy producers throughout the state of Illinois. The interview included questions regarding first line antimicrobial choices, disease indications, maintenance of medical records, existence of diagnostic and treatment protocols for common diseases, extent of veterinary involvement, understanding of the concept and consequences of extra label drug use, and familiarity with the concept of antimicrobial resistance. This data was used to identify common practices in antimicrobial use by producers, and their understanding and application of legal guidelines.

Subsequently, a questionnaire regarding producer demographics, current methods or resources used for continuing education, level of engagement in their work environment, and learning style preferences was administered to 187 livestock producers by face-to-face interviews at county fairs throughout Illinois. Survey responses were analyzed and examined for statistically significant responses based on gender, age, educational status, and level of engagement.

Results: Results from the initial survey identified key areas where educational intervention could have a significant impact: antibiotic selection/use of protocols, on-farm record keeping and extra-label drug use. Only 15% of those that responded indicated use of written treatment protocols on farm; 60% self-reported no protocols being used for treatment of disease. In conjunction, less than 50% of respondents could identify criteria that constituted extra-label drug usage (ELDU), with only 25% of producers seeking veterinary guidance when choosing to use an antimicrobial in an extra label manner.

The learning inventory demographics identified livestock producers from across the dairy (6.5%), beef (53%), small ruminant (32%) and swine (40%) production sectors, with some involved in more than one enterprise. The age range showed a bell-shaped curve centered on the 45-50 years, ranging from 18 to >71 years. More than 50% of respondents had completed some form of post-secondary education, and there was equal representation from laborers, animal health care providers and financial decision makers. Internet, magazines, and veterinarians were identified as the most common animal health information sources, and most producers identified themselves as strongly engaged in their work.

The learning styles of the participants could be classified into four learning categories, namely pragmatists, activists, theorists, and reflectors. While many producers demonstrated characteristics of multiple learning styles, there were clear patterns of preference associated with specific demographics.

Conclusions: The study showed areas of strength and weakness in knowledge, attitude, behavior and practice in antimicrobial usage in producers. To enhance the effectiveness of any training program, the principles of education must be used to design and deliver learning materials. Identification of weaknesses in using treatment records and protocols, and understanding ELDU, were identified as key components of an antibiotic training program. Understanding the prevalent learning styles, and their association with producer demographics, will be paramount in designing effective training activities and a healthy learning environment for livestock producers.

EDU-022-002

Abattoir feedback from veterinary students as a tool for herd health improvement

Pia Prestmo^{1,*}, Andrew Grist¹, Ed van Klink¹

¹University of Bristol, Bristol, United Kingdom

Objectives: According to EU legislation, conditions found at meat inspection are to be recorded by the Official Veterinarian (OV) if they "might affect public or animal health, or compromise animal welfare". Findings must be communicated back to the producer and their veterinarian. This flow of information is frequently used in the pig and poultry industry, but less accessed by cattle producers.

Bristol University's abattoir offers slaughter and butchery services to local farmers. A pilot project involving students on rotation investigated if and how inspection results are used to improve herd health, and how feedback may add to producers' knowledge.

Materials and Methods: Case reports produced by veterinary students during rotations were collected throughout 2015. These reports detail the results of an inspection performed by each student for one batch of animals. Each student presents their findings orally, and after discussion on what feedback will be useful for the producer, a written report is submitted and marked.

Each case report contains information collected at ante-mortem inspection (animal ID, producer details, loading times, clinical presentation, cleanliness, Food Chain Information) and from welfare assessment (stunning method, stun parameters, stun-to-stick times, and signs of successful stun). Post-mortem inspection is categorised into Carcass, Respiratory, Alimentary, Lymphatic, Circulatory, Skeletal, Muscular and Other. The student's findings and advice are sent to the producer, with advice to contact their own veterinary practice should they require further information.

A survey was conducted among the producers who received an advisory letter. The producers were asked whether the letter provided new knowledge, and whether they implemented any changes in their production system following the advice in the letter. Furthermore they were asked if they felt such a report added value to the service of slaughter provided by the abattoir, and if they would prefer to receive such reports also in the future.

An online survey was conducted among the students who had participated. The students were asked whether they believed this feedback was useful to the farmer, and how useful they felt it was as a learning experience.

Results: 41 case reports from cattle slaughtered at Langford Abattoir, School of Veterinary Sciences, were submitted in 2015. Most students reported no findings at ante-mortem inspection (68.3 % of reports), with the most common findings being signs of mild stress (14.6 % of

reports). All animals were found to be of adequate cleanliness. At post-mortem inspection the most frequent conditions observed were *Fasciola hepatica* (12.2% of reports), either as acute or chronic infection. Pleuritis (9.8 % of reports) and pneumonia (9.8% of reports) was seen in a few animals. However, most cattle slaughtered are young stock from local smallholders, and overall there were few disease findings observed.

Following receipt of the advisory letter, farmers have indicated that this gave an explanation for why organs had been condemned, that they had not received before. Condemnation of bovine livers for example, represent a loss of income, which warrants explanation. The abattoir does not regularly pass inspection results back to the farmers, as is the situation in many other UK slaughter plants (E. G. M. van Klink, P. G. Prestmo and A. Grist "Animal health and disease monitoring in the abattoir", *Livestock* Vol 20 (6), pp. 330-335).

Feedback from students has been overall positive, with students reporting the learning experience as useful. In particular, students indicate the benefit in having to produce a report that not only is marked by the tutors, but also gets sent to the client as a potential tool in herd health management.

Conclusions: Meat inspection results could be a useful tool for monitoring animal health on farm, especially for common subclinical conditions. There is great potential for improvement in the flow if this information, that may not have a high cost. Producers could use results together with their private veterinarian, e.g. to evaluate infection control strategies.

We aim to show students the potential which lies in this relationship between producer, veterinarian on farm and OV. We hope that new graduates who start working with food-producing animals will make use of inspection results, and that new networks may form between OVs and private veterinarians.

EDU-022-003

The Global Resource for Online Evidence-Based Veterinary Medicine Learning

Kristen Reyher¹,*Emma Crowther¹ Rachel Dean²Sarah Baillie¹Sebastian Arlt³Marnie Brennan²Dave Brodbelt⁴Fiona Brown⁵Douglas Grindlay⁶Ian Handel⁵Mark Holmes⁷Catherine McGowan⁸Timothy Parkin⁹Emma Place¹Gwen Rees¹Darren Shaw⁵Javier Sanchez¹⁰Laura Urdes¹¹John VanLeeuwen¹⁰Kristien Verheyen⁴ and Sheena Warman¹

¹University of Bristol, Langford, ²Centre for Evidence-based Veterinary Medicine, University of Nottingham, Nottingham, United Kingdom, ³Freie Universität Berlin, Berlin, Germany, ⁴Royal Veterinary College, London, ⁵University of Edinburgh, Edinburgh, ⁶University of Nottingham, Nottingham, ⁷Cambridge University, Cambridge, ⁸University of Liverpool, Liverpool, ⁹University of Glasgow, Glasgow, United Kingdom, ¹⁰University of Prince Edward Island, Charlottetown, Canada, ¹¹University of Agricultural Sciences & Veterinary Medicine Bucharest, Bucharest, Romania

Objectives: The evidence-based veterinary medicine (EBVM) Learning Consortium, an extensive international team with a collective passion for delivering high-quality teaching, has developed a coherent web tutorial designed to introduce learners to the key concepts of EBVM: www.ebvmlearning.org. This project brought together key stakeholders and experts to identify requirements for development of EBVM modules and to create online re-usable learning material. This tutorial will provide opportunities for students and members of the profession to engage in

EBVM, and will help ensure the topic is introduced well and adopted wholeheartedly by the profession.

Materials and Methods: EBVM Learning, funded by the Royal College of Veterinary Surgeons Knowledge Target Grants initiative, brought together a respected international team expert in the field of EBVM. Since knowledge of the theory, teaching, and practice of EBVM already existed at universities, this project team was made up of experts in the field, and also represented such diverse backgrounds as clinicians, scientists, researchers and experts in many areas of the veterinary profession. Collaboration, sharing and adaptation of the many resources already developed by individuals at a number of institutions was seen as the most powerful way to meet stakeholder needs and make a significant contribution to EBVM. An open-access, online tool explaining the basics of EBVM was created by marrying engaging content with accessible and usable technical design in order to encourage and facilitate re-use in a wide variety of familiar and unexpected settings as well as a number of platforms and devices. The resource was designed to utilise best pedagogical approaches, and included formative multiple choice questions, short tasks and recommendations for further study. It is intended to be a base of knowledge bringing together the basics of EBVM into one place, and highlights numerous other links to resources and organisations that are available to further learners' knowledge about the subject. Development of the resource followed an iterative cycle which included regular review by both the core team as well as other identified stakeholders (e.g. students, practitioners, industry representatives).

Results: An open access, online tutorial aimed at making EBVM accessible to the veterinary profession worldwide was successfully developed and launched in October, 2015. The resource begins with an introductory module – the ABCs of EBVM – and is then organised into modules addressing the five key areas of EBVM:

- 1 Ask - how to formulate answerable questions
- 2 Acquire - how to obtain relevant information
- 3 Appraise - how to evaluate the available evidence
- 4 Apply - how to apply the evidence to clinical practice
- 5 Assess – how to measure the effect of any implemented changes

The tool is appropriate for students and practitioners for self-study, and it is also envisaged that the resource will be used in whole or in part as standalone teaching modules to support other EBVM teaching or continuing professional development. The resource will offer the flexibility to be re-used in a variety of teaching and learning scenarios across the sector, or for independent learning. The tutorial also comprises a freely-available series of online, re-usable learning objects (videos, quizzes, case studies, exercises, worked examples and links basket, focussing on examples from various species) that runs the gamut from introducing basic terminology to providing detailed assistance with each of the steps in turn, in language accessible to practitioners who are keen to learn these techniques. This research highlights a specific learning tool, but also recognises a number of resources that are currently available to help farm animal practitioners employ EBVM.

Conclusions: Development of this resource has already increased awareness of EBVM in the veterinary profession, and allows practitioners the opportunity to develop the skills needed to utilise EBVM in everyday clinical practice. Future aims of the project team include designing methods of cataloguing and disseminating evidence syntheses to support clinical decision-making and evidence-based veterinary practice, improving and standardising the teaching of EBVM to undergraduate and postgraduate students at veterinary schools internationally and building a worldwide community of practice in the area of EBVM.

EDU-022-004

Developing a commercial herd health service to be used for undergraduate training

John Remnant ¹James Breen ¹Martin Green ¹Chris Hudson ^{1,*}¹School of Veterinary Medicine and Science, University of Nottingham, Loughborough, United Kingdom

Objectives: As part of the final year clinical rotations at Nottingham Vet school, a two week "herd health" rotation was developed to be undertaken by groups of 3-6 final year veterinary students. The goal of the rotation was to teach the principles of applied epidemiology and herd health to students using dairy farms as an example whilst also providing a chargeable consultancy service to commercial dairy farms. The aims of this project were to identify whether the Nottingham Vet School Herd Health Rotation has been effective in terms of:

1. Student satisfaction
2. Client satisfaction
3. Client performance

Materials and Methods: Farms were recruited to the service through the veterinary school's network of associate practices. The rotation has been running for 5 years with each farm visited by a different student group and academic members of staff approximately every 3-6 months.

Student feedback is formally collected at the end of each rotation using a scoring system standardised across all the final year rotations as well as gathering free text comments. Client feedback is collected via the associate practice and from direct feedback from the clients. Client performance is monitored as part of the service and farm management data is collated in TotalVet (QMMS/SUM-IT) analysis software allowing benchmarking and monitoring over time.

Results: Student feedback has been strongly positive, with the rotation consistently among the top scoring clinical rotations in every area evaluated. Example free text comments are included below:

"Enjoyed this rotation much more than I thought I would as cows and stats aren't really my deal but it was great. It was really well structured with a good encouraging staff support network"

"This rotation gave our group a great opportunity...had a real impact on the herd and on the farmers business"

"Everything suddenly came together when we started looking at our farm and then discussing our findings for the farmer"

Weaknesses identified and improved mainly relate to the logistics of delivering the rotation, although additional sessions have been added to cover further topics.

Client satisfaction appears good, with clients keen to remain in the scheme and requesting visits. As in private practice, this type of service is not suited to all clients, and there was some initial "drop-out" from farmers. Some farms were not considered appropriate to remain in the service due to poor compliance or data quality.

Client performance is good and continues to improve. Some example findings are included below:

"10 cows that previously scored sound (0 or 1) have been scored lame (2 or 3) in May; these are likely NEW lameness and must be prioritised for treatment"

"the rate of new clinical mastitis cases occurring less than 30 days into lactation (i.e. cases from likely dry period origin infections) has been very well controlled following our discussions ... averaging less than 1 in 12 animals affected"

Conclusions: Whilst this service has been and continues to be refined, the authors consider the rotation a success. Student and client feedback is positive and there has been demonstrable improvement in farm performance.

This demonstrates that it is possible to provide a chargeable herd health service alongside the provision of good quality training in herd health to undergraduate veterinary students.

Further case studies and examples will be presented.

EDU-022-005

Training clinicians to make the most efficient use of new data: an evidence-based Bayesian approach

Helen M. Higgins ^{1,*}Richard L. Cooper ²Wendela Wapenaar ³¹University of Liverpool, Leahurst Campus, Neston, ²Evidence Based Veterinary Consultancy, Rural Enterprise Centre, Cumbria, ³School of Veterinary Medicine and Science, University of Nottingham, Loughborough, United Kingdom

Objectives: Evidence-based veterinary practice relies heavily on the abilities of clinicians to update their current clinical approaches logically when presented with new evidence. However, the psychological, behavioural and economic literatures suggest that people may react negatively (cognitively, behaviourally, emotionally) when presented with new data.

Aims: (i) to demonstrate a simple practical method for capturing vets clinical beliefs as probability distributions, pre- and post- exposure to new data (ii) to quantitatively assess how logically vets update their beliefs by comparing them to a gold standard: predictions from Bayes theorem

Materials and Methods: In total, 40 vets were interviewed for 30 minutes, face-to-face. Voluntary consent was obtained. A standard script was used and piloted on 3 vets; their data is not included. The clinical context was over-conditioned heifers (body condition score > 3.75) calving down at ≥ 27 months old. The elicited parameter, θ , was the probability of dystocia for this population of heifers when receiving a ruminal bolus of monensin 28 days pre-calving to prevent ketosis, conditional on a 0.5 probability of dystocia without monensin. After a short training exercise, vets expressed their current beliefs for θ as a probability distribution (prior belief) using a version of the roulette method; they placed 20 chips, each worth 0.05 probability in 0.05 discrete intervals over the range of θ . Next, vets were shown data from a small (n=50) clinical trial that challenged their prior belief: if the prior mode was >0.5, data had a point estimate = 0.34 with 95% confidence interval (CI) of 0.22-0.48; if prior mode <0.5, data = 0.66, CI 0.52 - 0.78. Their updated belief after seeing the data was captured as a probability distribution (first revised belief). Finally, they were shown corroborating data from a large, n=1000, trial: data=0.34, CI 0.32-0.38 or 0.66, CI 0.62 - 0.68). Their updated beliefs were then captured again (second revised belief). A conjugate Bayesian analysis was used to calculate, per vet, the logical belief after seeing the first and second trial data. Statistics reflecting central tendency and dispersion of the distributions quantified how logically vets updated their beliefs.

Results: Prior beliefs: Of the 40 vets, 15 had a prior mode >0.5 and 25 had a prior mode <0.5. There was notable heterogeneity in the prior beliefs, both in terms of central tendency and dispersion of their distributions, indicating diversity in current clinical opinion regarding θ . Many vets had non-overlapping prior 95% Bayesian credible intervals.

Changes in central tendency: After seeing the first study results, only 3 vets centred their beliefs perfectly logically. The majority (30/40=75%) moved their centre of locations closer to the data than was logical i.e with respect to where they centred their distributions, they gave more weight to the evidence from the small study than was logical. The remainder (7/40=18%) failed to move sufficiently close i.e they under-valued the new information. In contrast, after seeing the second trial results, 16 vets (40%) moved their centre of location perfectly logically.

Changes in dispersion: After seeing the first study results, the majority (30/40=75%) had less confident beliefs (larger standard deviations) compared to their prior beliefs, i.e. they became more uncertain after seeing the results of the new study than they were before; this is a major departure from Bayesian logic. In contrast, after seeing the second trial results, vets were notably more logical; 35 (88%) had revised distributions with smaller standard deviations relative to their prior. However, given the strength of the new evidence, the majority still remained more uncertain than was appropriate.

Conclusions: Results suggest that some vets may benefit from additional training to help them update their clinical beliefs appropriately when presented with new data. By reflecting on how they revise their beliefs compared to Bayesian logic, vets can learn how best to weigh the value of new data, in the context of their own prior beliefs. The roulette method is a simple practical way to quantify vets' beliefs pre- and post-exposure to new data and could be developed into an on-line training tool. This type of training would be of value to both undergraduates and postgraduates, and will help facilitate the efficient transfer of new evidence into practice.

ED-026-001

Prevalence And Distribution Of Exposure To Schmallenberg Virus In Irish Cattle During November 2012 To November 2013

Damien Barrett¹,*Bernard Bradshaw² Micheal Casey² Ronan O'Neill² Simon More³ Donal Sammin²

¹Sligo RVL, Dept of Agriculture, Food and the Marine, Sligo, ²Dept of Agriculture, Food and the Marine, ³University College Dublin, Dublin, Ireland

Objectives: As Ireland was on the margins of the epidemic in Europe it was uncertain as to how Schmallenberg virus would spread, although given the spread of SBV in several European countries in, it was anticipated that SBV would spread north-west wards during the 2013 vector season. The objectives of this study were to determine the level of exposure among the Irish cattle population initially at the end of 2012 and to document the spread of SBV in Ireland over the course of the 2013 vector season.

Materials and Methods: Samples of brain or external foetal fluids from cases of abortion or still birth submitted to the Dept. of the Agriculture's passive veterinary surveillance system. These cases had suspect lesions such as hydranencephaly or arthrogryposis were tested using a real-time reverse transcription rRT-PCR detecting an 88bp fragment of the S3-segment of the SBV genome developed at the Friedrich-Loeffler Institute. Three national serosurveys were conducted to estimate SBV exposure in Irish cattle, using sera collected between November 2012 and November 2013, as part of the national brucellosis eradication programme. At the first, second and third SBV serological surveys, samples were collected from 3,192 cattle from 529 herds, 3,101 samples from 517 herds, and 3,204 samples from 534 herds, respectively. Sera were screened using a commercially available SBV Antibody Kit (Idexx Laboratories). Data were managed and analysed using Microsoft Excel (Microsoft Corporation, Redmond, WA, USA) and ArcGIS 9.1 (ESRI, Redlands, CA, USA).

Results: Between October 2012 and May 10th 2013, SBV was confirmed by qRT-PCR in brain tissues from 49 malformed bovine fetuses in Ireland. These herds were geographically distributed in the south, south east and east of the country. The overall herd seroprevalences in the three surveys varied from 51.4% to 53.3%, and the overall animal level prevalence was also consistent over the course of the three surveys, ranging from 32.2% to 35.8%, both of which were remarkably consistent, with the greatest rates of seroconversion in the south, south east and east. Herd seroprevalence in counties ranged from 0% to 100%, with the counties in the south and southeast having the highest seroprevalence (>50%), the midlands a moderate seroprevalence (10-50%) while the northern and northwestern counties had a low seroprevalence(0-10%).

Conclusions: The areas with the greatest SBV seroprevalence coincided with the area where SBV was detected by PCR in brain tissue of malformed bovine fetuses. Given the inactivity of the virus since 2012, it is likely that the younger age cohort in herds where SBV was previously endemic are now immunologically naive, and would be susceptible if the virus were to be re-introduced into Ireland. Likewise, substantial proportions of animals on the margins of affected areas have been reported as immunologically naive to SBV, and susceptible to infection if the virus was re-introduced into the country.

ED-026-002

Failure to define the aetiology of acute respiratory disease in thirteen of fifteen live dairy cows in Scotland.

William Crawshaw¹,*Paul D. Williams²

¹MBM Veterinary Group, Kilmarnock, ²MSD Animal Health, Milton Keynes, United Kingdom

Objectives: To investigate the aetiology of naturally occurring acute respiratory disease in fifteen live dairy cows on different farms by laboratory examination of bronchoalveolar lavage (BAL) samples, nasopharyngeal swabs, faeces and paired serology using standard laboratory techniques.

Materials and Methods: Previously untreated dairy cows presented for veterinary treatment in a first opinion veterinary practice in Scotland showing clinical signs consistent with acute pneumonia and meeting inclusion criteria designed to maximise the probability of selecting acute cases were admitted to the study. Suitable tubing for BAL sample collection became unavailable after case 8. Samples were examined for infection with the 3 respiratory viruses bovine herpes virus 1(BoHV-1) (nasopharyngeal swab) and bovine respiratory syncytial virus (BRSV) and parainfluenza virus 3 (Pi3) (BAL sample in 8 cases and nasopharyngeal swab in 7 cases). Bacteriology and Mycoplasma spp. culture (BAL sample in 8 cases and nasopharyngeal swab in 7 cases) was also performed. Faeces were examined for lungworm larvae. Paired serology was conducted for BoHV-1, BRSV, Pi3, BVDV and Mycoplasma bovis. Standard laboratory techniques were employed. Clinical signs, case history (including vaccination), treatment and response to therapy were also recorded.

Diagnostic criteria: For the respiratory pathogens (BVDV excluded) demonstration of a pathogen in a BAL sample or nasopharyngeal swab by polymerase chain reaction or virus isolation for viruses or culture for bacteriology or Mycoplasma spp. and detection of lungworm larvae in faeces by Baermann technique. Sero-conversion to the viruses or Mycoplasma bovis would provide supportive evidence provided there had been no previous vaccination with the pathogen in question within 6-weeks of acute sample collection.

Results: Fifteen cases meeting the case inclusion criteria from 10 different farms were sampled between April 2013 and June 2015. Rectal temperature range was 39.3 to 41.4 °C (mean 40; median 39.8; interquartile range 0.55). All cases showed a clear nasal discharge, tachypnoea and harsh respiratory sounds. In 7 cases adventitious lungs sounds were present and in 2 coughing was recorded. No ocular discharge was recorded. Cases 6 and 8 also showed metritis; otherwise no concurrent disease was detected. All cows were Holstein/Friesian, none were in lactation 1 and 3 were in lactation 2 whilst the remainder were in lactation 3 or more. Case 5 was euthanased before an acute blood sample could be collected due to poor treatment response. Of the remaining 14 cases, 2 (cases 6 and 14) had responded poorly to treatment when the convalescent sample was collected whilst the remainder had significantly improved clinically. Diagnosis of a respiratory pathogen was made in only 2 of the 15 cases sampled. Mannheimia granulomatis (historically this would have been identified as Mannheimia haemolytica) in case 3 and Mannheimia haemolytica in case 6 were recovered from BAL samples and case 6 also seroconverted to BVDV. Case 14 seroconverted to BoHV-1 but the virus was not detected. The other 2 seroconversions (to BoHV-1 and BVD) were associated with vaccination.

Conclusions: The failure to confirm a diagnosis in 13 of 15 live cases of acute pneumonia is of interest since the case inclusion criteria were designed to sample acutely infected cattle where any primary pathogen(s) should have been detectable or caused seroconversion.

The failure to culture *Trueperella pyogenes* from any case tends to confirm that chronic cases were not selected.

Comments: The two diagnoses of *M. granulomatis* and *M. haemolytica* are consistent with previous reports of pneumonia in dairy cows investigated at necropsy in the United Kingdom. However, the cases reported here were investigated when they were alive and 12 of 15 responded to treatment and survived so they may represent a different category of diseased animals. The pneumonia in case six may have been secondary to immune suppression caused by BVD virus infection.

The failure to achieve a laboratory diagnosis in 13 of 15 cases challenges current standard laboratory procedures. Maybe the laboratory tests used were insufficiently sensitive or the aetiology was not infectious. Alternatively, the clinical diagnoses may have been incorrect. However, most of the cows responded to treatment for respiratory disease with macrolide antibacterials suggesting that this was unlikely. Most likely, the acute pneumonia was caused by pathogens which are either unknown or not currently routinely tested for and therefore not recognised as significant. It is suggested that further investigation of acute respiratory disease in dairy cows is required to include a broader range of potential respiratory pathogens including unknown and known potential pathogens such as coronavirus and influenza virus.

ED-026-003

Epidemiological Analysis Of A Novel Disease Associated With A New Variety Of Swede In Southern New Zealand

Mark Bryan¹, *Shen-Yan Hea², Shana Wilkinson³, Debbie McCorkindale⁴

¹Head of R&D, ²Epidemiologist, ³Economic Analyst, ⁴Head of Tech Services, VetSouth Ltd, Southland, New Zealand

Objectives: During the winter of 2014 in Southern New Zealand, an unusual pattern of disease and mortality appeared amongst dairy cows grazing on, or with previous exposure to, brassica spp.

The winter of 2014 saw a novel type of swede widely introduced to the market ('HTTM'), and the clinical picture suggested a link between this swede and increased disease and mortality.

This study was a broad epidemiological study that attempted to gather together clinical case series, biochemical analyses, and proportional mortality data to ascertain any association between the novel swede and both disease and mortality.

Materials and Methods: Case series information gathered during this emerging disease included autopsy data from acute deaths, alongside clinical disease and associated biochemical and haematological analyses.

Furthermore, cohort biochemical analyses were performed on adult cows grazing adjacent but different brassica spp; and temporally controlled serological analysis was performed on a group of young heifers (12 months old) assessed prior to, during, and after exposure to the postulated risk factor (the novel swede variety).

Biochemical analysis of peri-parturient (pre partum, colostrum, and milking) exposed and non-exposed cows was also undertaken from a number of affected herds.

Finally, a retrospective analysis was undertaken to measure mortality rates from a large number of herds and cows grazing on a variety of winter grazing options. Farmers were interviewed to gather winter

grazing data, including the type of crop, the day of arrival and of leaving, and the numbers of animals arriving or leaving.

These objective data provided simple mortality rates for separate groups of cows grazing on different forages. Exposure was calculated and a mortality rate (number of deaths/100 cows/100 days) was calculated for each forage.

Relative Risk (RR) and Odds Ratio (OR) were calculated. Then, a Generalised Estimating Equation (GEE) was used, with crop type nested within farm.

The outcome variable was mortality rate (deaths/100cows/100 days), as a linear scale function; and the risk factor was crop type. The model used an independent working correlation matrix and estimated marginal means (EMM) were calculated

Results: The clinical picture was of cows developing a wide variety of symptoms, including inappetence, photosensitivity, non-specific disease and in some cases non-responsive recumbancy. Autopsies typically showed gross liver pathology with histopathological evidence of peri-biliary pathology.

Biochemical analysis amongst clinically affected animals demonstrated vastly elevated liver enzymes (GGT, GLDH, AST); analysis of exposed and unexposed cows showed differences in the same enzymes; and analysis of youngstock showed significant elevations in GGT and GLDH once exposed to HTTM swedes.

When compared with all other winter grazing options, the OR of death on HTTM swedes was 2.29; and the RR of death was 2.28. When HTTM swedes were compared with only other brassica spp (including an HTTM mix), the OR of death on HTTM swedes was 6.15; and the RR of death was 6.11.

Winter crop type had a significant effect on mortality rate ($p < 0.001$). The overall mean MR was 0.64% (95% CI 0.62-0.87). Amongst the key brassica and winter crop types, HTTM swedes had a mortality rate of 2.04% (95% CI 1.64- 2.44); kale was 0.25% (95% CI 0.20- 0.31); and fodder beet was 0.25% (95%CI -0.04-0.55).

Conclusions: These data corroborate the initial clinical hypothesis that there was a significantly higher risk of mortality among adult dairy cows grazing on HTTM swedes during the winter of 2014 than among cows on any other type of forage, irrespective of management or cause of death.

The biochemical, clinical and autopsy data help to confirm that cows developed significant liver disease when grazing the novel swede variety which lead to severe clinical disease and an increased risk of mortality.

These data have helped inform industry advice on the best practice use of this novel swede variety.

ED-026-004

Bovine respiratory pathogens in France: prevalence and new virus discovering

Elias Salem¹, *Nicolas Herman², Mariette Ducatez³, Gilles Meyer²

¹INRA-ENVIT, UMR1²²⁵ IHAP, ²College of Veterinary Medicine of Toulouse - France, ³INRA, UMR1²²⁵ IHAP, Toulouse, France

Objectives: Bovine respiratory disease (BRD) is among the most prevalent pathological conditions in young cattle involving complex interactions between pathogens (virus, bacteria) and environmental or farm management factors. The exact prevalence of each pathogen

and the frequency of co-infection in the different production systems are however still unclear. The objectives of the present study were to use new technologies, next generation sequencing (NGS) and real time PCR (qPCR) or reverse transcription-PCR (RT-qPCR), to best characterize the prevalence of respiratory pathogens in French breeder systems and to identify new respiratory viruses.

Materials and Methods: Nasal swabs (NS) and bronchoalveolar lavages (BAL) were collected from a total of 21 breeding herds with BRD between 2013 and 2015. Four to five calves per herd, not treated with antibiotics, were sampled at the acute phase of infection (< 3 days). After RNA and DNA extraction, BAL and NS samples were tested by real time PCR (Taqvet respiratory pathogens, Lifetechnologies) for bovine respiratory syncytial virus (BRSV), parainfluenza 3 virus, bovine coronavirus (bCoV), bovine viral diarrhoea virus (BVDV), *Pasteurella multocida*, *Mannheimia haemolytica*, *Histophilus somni* and *Mycoplasma bovis*. These samples were also screened by a systemic NGS approach using Illumina Miseq technology. According to results, field respiratory specimens (NS, trans-tracheal aspiration, BAL or lung tissue) obtained between 2010 to 2015 from 134 acute respiratory outbreaks in young cattle were tested by real-time reverse transcription-PCR (RT-qPCR) for influenza D virus (IDV) as previously described (Hause et al., PLoS pathogens. 2013;9(2):e1003176). One specimen with the lowest cycle threshold (CT value) was selected for further molecular characterization and its full genome was amplified by PCR and sequenced on a 3130XL Applied Biosystems capillary sequencer. Determination of IDV seroprevalence was done by hemagglutination inhibition assay.

Results: Results on BAL showed a high frequency of co-infections with 2 to 4 pathogens identified in more than 40% of the outbreaks. No specific associations were found; co-infections involved bacteria and virus or virus-virus or bacteria-bacteria. BRSV and BCoV were the most frequently viruses detected in the lower respiratory tract, alone or in association (27% and 42%, respectively). The included pathogens were more frequently detected in upper respiratory tract except for BRSV and *M. bovis* with respectively 26.3% vs 5.3% and 10.5% vs 5.3% frequency in BAL vs NS. Finally 2 of 21 outbreaks remained negative for all tested pathogens. NGS results showed the presence of new viruses in each type of samples. Particularly a new putative respiratory pathogen, called Influenza D virus (IDV) was identified by RT-qPCR in 6 samples (4.5%) out of 134 French field isolates collected between 2010-2014, with CT values ranging from 15 to 35. Co-infections were detected with major pathogens in 4 of the IDV positive specimens. However two samples collected in 2014 were negative for all tested respiratory pathogens, despite reports of clinical signs in the animals. A preliminary serological study (200 bovine sera tested in the region where IDV was detected) indicated a high seroprevalence, with 83% of positive samples. Finally the French IDV complete genome was 94-99 % identical to its American and Chinese counterparts, suggesting a common origin of these new influenza viruses. The estimated ranges of evolutionary distances between French and United States IDV ranged between 0.8 and 5.7%.

Conclusions: French cattle are frequently co-infected with respiratory pathogens although no clear pattern of specific associations was found. Conversely, absence of pathogen detection in respiratory samples suggests that some unknown agents, especially viruses, may be involved in BRD. Recent studies proposed bovine nidovirus, rhinovirus type A or adenovirus type 3 as putative respiratory pathogens. Here we have identified a novel influenza D virus in cattle with respiratory symptoms. Further studies are tough warranted to assess the emergence threat of IDV viruses in Europe, and at providing essential information about the pathogenicity of IDV in cattle.

ED-026-005

Bovine Besnoitiosis: The First Diagnosis of this Emerging Disease in the Republic of Ireland

Eoin Ryan¹, *Alison Lee² Catherine Carty¹ James O'Shaughnessy¹ Pamela Kelly² Joseph Cassidy² Maresa Sheahan³ Alan Johnson⁴ Theo deWaal⁵

¹Farm Animal Department, ²Veterinary Pathology Department, University College Dublin, Dublin⁴, ³Kilkenny Regional Veterinary Laboratory, Department of Agriculture, Food and the Marine, Kilkenny, ⁴Limerick Regional Veterinary Laboratory, Department of Agriculture, Food and the Marine, Limerick, ⁵Veterinary Parasitology Department, University College Dublin, Dublin⁴, Ireland

Objectives: Bovine besnoitiosis, caused by *Besnoitia besnoiti*, was diagnosed in a dairy herd in Co. Tipperary, Republic of Ireland. This is the first diagnosis of this disease in Ireland or the UK. The objective of this abstract, and the associated presentation, is to document the discovery of this disease in the Republic of Ireland and to reinforce the classification of bovine besnoitiosis as an emerging disease in Europe (EFSA 2010).

Materials and Methods: The diagnosis of besnoitiosis occurred following an investigation on June 19th 2015 into a problem of suspect photosensitisation occurring on a dairy farm since 2010. A number of cows in the herd had clinical signs including thickened skin, alopecia, weight loss and poor milk production. Other cases were described as having clinical signs including pyrexia, swelling of the limbs, respiratory disease and milk drop syndrome which persisted for a period of 2 to 3 weeks. A clinical and epidemiological investigation was carried out on the farm which included taking skin biopsies from severely affected cows.

Results: Skin biopsies carried out on five cows were confirmed to have granulomatous and eosinophilic dermatitis with characteristic large intradermal protozoal cysts consistent with a diagnosis of cutaneous besnoitiosis caused by *Besnoitia besnoiti*. A follow-up investigation was carried out, in conjunction with the Department of Agriculture, Food and the Marine, which involved serological testing and clinical examination of 228 animals on the farm. Serological testing, carried out in the Friedrich Loeffler Institute in Germany, found that 68% (144/212) of animals were ELISA antibody positive for *Besnoitia besnoiti*. In addition, 51% (117/228) of animals had characteristic cysts on the scleral/bulbar conjunctiva (sclerocysts). The prevalence of vulval cysts was 68% (134/198), but there was poor reproducibility and agreement between individual examiners in terms of the identification of vulval cysts. This contrasted with the high level of agreement and reproducibility of results when assessing eyes for the presence of sclerocysts.

Conclusions: The clinical and serological results confirm that this herd is endemically infected with *Besnoitia besnoiti*. It is likely that cases of besnoitiosis have been occurring on this farm since at least 2010. Further epidemiological investigation is on-going to identify the original source of besnoitiosis for this herd and when the disease entered the herd. The identification of this previously exotic disease highlights the importance of disease surveillance at the national and local practitioner level, particularly with respect to emerging diseases in Europe.

EP-034-001

Spatial Differences in the Prevalence of Diseases in a Veterinary Practise

Michael Hässig^{1,*}, Dorothee Depka¹, Gianluca Boo²¹Farm Animals, ²Institute for Geography, University of Zurich, Switzerland, 8057 Zurich, Switzerland

Objectives: To our knowledge, no analysis has been performed for the catchment area of a single veterinary practice so far. At this local scale, spatial data on disease prevalence can be collected, processed, analysed, and visualised to detect meaningful patterns and validate potential etiologies. In our study, we used a Geographic Information System (ArcGIS®) to represent the spatial distribution of specific diseases among the cattle located in the catchment area of the ambulance servicing the animal hospital of Zurich, Switzerland. In doing this we also assessed linkages between disease prevalence and potential geographical risk factors.

Materials and Methods: We conducted a retrospective study on the prevalence of specific cattle diseases within the catchment area of the ambulance servicing the animal hospital of Zurich. The study window spans between the 1.1.2013 and 31.12.2013, and data has been acquired through the software managing the veterinary hospital services (Oblon®). The cattle at-risk has been estimated based on the records stored in the Swiss animal movement database (TVD) from 1.6.2013. For our study purposes, we used geographical data issued from the Swiss federal office of topography (swisstopo) in 2014, such as background maps, water bodies, road networks, land uses, and altitudes. We defined the individual diseases based on the diagnoses performed at the animal hospital of Zurich and then performed a Kriging analysis to produce prevalence-density surfaces for each disease. The following diseases have been examined: metritis/endometritis, papillomatosis, prolapse uteri, puerperal disease, reproduction problems, retentio secundinarum, torsio uteri, endoparasitosis, foreign body disease, hypocalcemia, ketosis, claw disease, coccidiosis, cryptosporidiosis, and mastitis. Additionally, we evaluated the impact of specific geographical risk factors such as proximity to water bodies, major roads, and altitude.

Results: This study aims at assessing the spatial distribution of the prevalence of specific cattle diseases in the catchment area of a single veterinary practice. The study region is located within the catchment area of the ambulance servicing the animal hospital of Zurich in 2013, which consists of 124 farming companies rising between 20 and 50 cows. The surface investigated is of about 60 square-kilometers and it is located north of the city of Zurich. We performed density surface, cluster and case-control analyses of multiple thematic layers (i.e., disease types and geographic risk factors). Preliminary results suggest that certain parasitoids, especially fasciolosis, could be associated with proximity to water bodies, i.e. rivers, lakes and ponds. Mastitis could also be related to the proximity of wood storage places and forests. Claw disorders could be associated with increasing altitude. However, these findings have to be further validated and bias and confounders should be investigated in depth.

Conclusions: Small-scale risk maps are a useful tool to detect meaningful patterns and validate potential etiologies as well as implementing preventive measures. The implementation of preventive measures associated with the geographical context would reduce the resources employed for cattle diseases treatment, by limiting the costs associated with antibiotic resistance without affecting the cattle health.

EP-034-002

Genetic diversity and antibiotic resistance of E. coli isolates from NCD cases in Uruguay

Ana Umpiérrez^{1,*}, Martín Oliver¹, Inés Bado², Sofía Acquistapace¹, Analía Etcheverría³, Nora L. Padola³, Rafael Vignoli², Pablo Zunino¹¹Departamento de Microbiología, Instituto de Investigaciones Biológicas Clemente Estable, ²Departamento de Bacteriología y Virología, Instituto de Higiene, Facultad de Medicina, Universidad de la República, Montevideo, Uruguay, ³Laboratorio de Inmunología y Biotecnología, Facultad de Veterinaria, Universidad Nacional del Centro de la Provincia de Buenos Aires, Tandil, Argentina

Objectives: Neonatal calf diarrhoea (NCD) is a severe infectious disease that affects neonatal calves in Uruguay. High morbidity and mortality rates and the associated economic burden are substantial all over the world. *Escherichia coli* is one of the aetiological agents of NCD, mainly affecting calves in the first hours of life. Genotypic characterization and antibiotic resistance patterns of *E. coli* strains are needed for epidemiological knowledge of NCD.

The aim of this study was to evaluate the genetic diversity, clonal distribution and antibiotic susceptibility patterns of a collection of *E. coli* isolates recovered from calves in Uruguay.

Materials and Methods: A collection of 304 *E. coli* isolates from calves' faeces younger than 35 days-old in Uruguay were analyzed. The collection, generated between 2012 and 2014, included *E. coli* strains recovered from animals affected with NCD and healthy animals at the moment of sampling.

Clonal diversity was analyzed by rep-PCR and multilocus sequence typing (MLST). All isolates were typed using ERIC-PCR whereas 22 *E. coli* strains were selected for multilocus sequence typing (MLST). Selection criteria of strains included previous PCR assays performed to determine the presence of adhesins and toxins genes, presence and absence of symptoms of NCD and geographical origin of the animals.

Dendograms were constructed to establish clonal relationships between ERIC-PCR band patterns by the neighbor-joining method (tolerance 1%, optimization 1%). MLST was performed following the guidelines in the MLST database (<http://mlst.warwick.ac.uk/mlst/dbs/Ecoli/>) and concatenated sequences of the 7 genes of each strain were used to construct a dendogram by the neighbor-joining method.

For selected isolates, the presence of class 1 integrons (C1I) was determined by PCR using I5'-I3' primers. The variable regions (VR) were elucidated by PCR and sequencing with primers 5CS and 3CS.

Resistance to fluoroquinolones (FQ) and oxyiminocephalosporins were evaluated by the ability to grow in Müller Hinton agar plates supplemented with Ciprofloxacin (0.125 µg/ml) and Ceftriaxone (1.0 µg/ml) respectively. *E. coli* ATCC 25922 was used as control. Results interpretation was completed after 24 h of incubation at 37 °C.

Results: ERIC-PCR analyses showed a high genetic heterogeneity. We observed that different genetic variants were present within farm-outbreaks. Also, the same genetic variants were observed in animals with symptoms and without symptoms of the disease. Moreover, it was observed that same genetic variants were circulating in severe outbreaks from neighbor farms. Seventeen different circulating ST were identified, including 4 novel ST. All detected ST were reported from bovine samples, as well as other origins except for ST1087 which was exclusively reported in bovine samples. Particularly, same clone and ST was found in 2 isolates from a single farm. These isolates were from an animal with symptoms of NCD and another animal without symptoms of the disease.

C11 were detected in 5/22 *E. coli* isolates and the variable region showed the following gene cassette arrangement: *dfrA7*; *dfrA17*-*aadA5*; *dfrA1*-*aadA1* and *dfrA12*-*orfF*-*aadA2*.

Concerning antibiotics resistance, 43.8 % of the 304 *E. coli* isolates were resistant to Ciprofloxacin and 6.3 % to Ceftriaxone; 2.0 % were resistant to both Ceftriaxone and Ciprofloxacin.

Conclusions: Several *E. coli* genetic variants with diarrhoeagenic potentiality for cattle were detected in Uruguay. In total, 17 ST were identified, including 4 novel ST. ST29 and ST69 complexes, widely distributed in bovine and human were detected.

Diversity results demonstrated that factors like the status of the animal, environmental conditions and occurrence of others pathogens individually or together, could have a role in NCD development.

Finally, a large number of strains were resistant to FQ and the presence of C11 explain resistance to co-trimoxazole and aminoglycosides confirming that antibiotic resistance is an increasing problem in livestock.

EP-034-003

A systematic review and meta-analysis of clinical mastitis recurrence in dairy cows

Hossein Jamali ^{1,*}, Herman Barkema ², Mario Jacques ¹, Eve-Marie Lavallée-Bourget ¹, François Malouin ³, Vineet Saini ², Henrik Stryhn ⁴, Simon Dufour ¹

¹Département de pathologie et microbiologie, Faculté de médecine vétérinaire, Université de Montréal, Saint-Hyacinthe, ²Department of Production Animal Health, Faculty of Veterinary Medicine, University of Calgary, Calgary, ³Département de Biologie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke, ⁴Department of Health Management, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Canada

Objectives: A high proportion of cows with a clinical mastitis (CM) case will experience repeated CM events within the same lactation. It is not clear, however, whether CM risk following a first CM event is decreased (i.e. efficient immunity), maintained, or increased (i.e. greater susceptibility). Objective of the current study was to compare risk of subsequent CM in cows that already experienced a first CM in the current lactation to risk of CM in healthy cows.

Materials and Methods: The study design was a systematic review and meta-analysis of the literature. Three databases were searched for original studies describing CM recurrence. Articles focusing strictly on first parity cows and articles not following cows for their complete lactation were excluded. In each article, data regarding total number of lactations followed and number of lactations with ≥ 1 and ≥ 2 CM cases were extracted. The source of data used in each study (i.e. prospective data collected specifically for the study vs. use of an existing database) and CM recurrence case definition (i.e. the minimal number of days between two episodes of CM to consider them independent cases) were also extracted. For each study, a risk ratio (RR) measure comparing risk of subsequent CM cases in cows having already experienced a first case in the current lactation to that of healthy cows was computed with 95% confidence intervals (CI). Summary RR across studies were computed using random effect models. Putative sources of heterogeneity were investigated using subgroup analyses and univariate meta-regression.

Results: A total of 1,666 abstracts were reviewed; nine studies were included in the meta-analysis (see references). In three studies, CM

data were collected from existing databases. Three studies used ≤ 24 h between cases as minimal lag time between events and six studies used values ranging from five to 21 days. Individual studies RR ranged from 0.83 to 2.1. Important heterogeneity between studies was noted. Results from the univariate meta-regression indicated that source of CM data used explained only 3.9% of the between studies RR variance. The minimal lag time between two independent CM cases (categorized as ≤ 24 h vs. ≥ 5 days), however, explained a substantial proportion (62.2%) of the between studies RR variance. Summary RR of 1.5 (95% CI: 1.2, 2.0) and of 0.99 (95% CI: 0.86, 1.1) could be computed for studies using minimal lag times of ≤ 24 h, and ≥ 5 days, respectively.

Conclusions: Our results suggest that cows are, at the very least, equally susceptible to CM after a first case. Clinical mastitis case definition, however, appears to substantially affect the computed RR. Most important heterogeneity was noted when comparing studies using ≤ 24 h to that using ≥ 5 days between cases.

EP-034-004

Evolution of the nasopharyngeal microbiota of beef cattle from weaning to 40 days after arrival at a feedlot

Edouard Timsit ^{1,2,*}, Matthew Workentine ³, Anthony Schryvers ⁴, Trevor Alexander ⁵

¹Production Animal Health, University of Calgary, Faculty of Veterinary Medicine, Calgary, ²Feedlot Health Management Services, Okotoks, ³University of Calgary, Faculty of Veterinary Medicine, ⁴University of Calgary, Faculty of Medicine, Calgary, ⁵Lethbridge Research Centre, Agriculture and Agri-Food Canada, Lethbridge, Canada

Objectives: Bovine respiratory disease (BRD) is a major cause of morbidity and mortality in beef cattle. Whereas host immunity is important in controlling overgrowth of bacterial pathogens in the nasopharynx, there is recent evidence suggesting that the nasopharyngeal microbiota has a key role in respiratory health. However, there is a paucity of knowledge regarding evolution of nasopharyngeal microbiota when cattle are most likely to develop BRD; from weaning to 40 d after arrival at a feedlot.

The objective was to describe the composition of the nasopharyngeal microbiota of beef cattle and its evolution from weaning to 40 d after arrival at a feedlot.

Materials and Methods: Deep nasal swabs (DNS) from 30 Angus-cross steers were collected at weaning, on arrival at a feedlot, and at 40 days after arrival. The DNA was extracted from DNS and the hypervariable region V3 of the 16S rRNA gene was amplified. The 16S rRNA gene amplicons were then sequenced using the MiSeq reagent kit v2 (500 cycles) on the MiSeq platform (Illumina, Inc., San Diego, CA, USA). Sequence data were processed using a custom Snakemake pipeline (<https://bitbucket.org/mlworken/microbiome-pipeline>) based on the UPARSE pipeline using USEARCH v8.0.1623. Downstream analysis was performed in R (R Core Team 2015, Vienna, Austria) using functions from phyloseq, DESeq2, and vegan. Intra-sample diversity (α -diversity) was calculated using observed species and the Shannon diversity index; α -diversity between groups was compared with a Kruskal-Wallis Rank Sum test (using $p < 0.05$ as a cutoff for significance). The OTUs that changed over time were identified using a generalized linear model as implemented in DESeq2.

Results: A total of 10,494,168 sequences were obtained across all samples, with a total length of 175 bases per read post-processing, and an average coverage of 111,640 sequences per sample (range = 2,911-314,407). Sequences were clustered into 1342 OTUs (excluding singletons) across all samples.

In total, 16 phyla were identified, although 87.9% of the total abundance belonged to Tenericutes (53.2%) and Proteobacteria (34.7%). The remaining phyla that each comprised $> 1\%$ of OTUs were Firmicutes (4.2%), Bacteroidetes (3.7%) and Actinobacteria (3.4%). Within Tenericutes, 99.8% of the abundance was assigned to a single genus; *Mycoplasma*. BLASTing the most abundant OTUs that were classified within this genus showed that *Mycoplasma dispar* was the most prominent species (78.5 % of the abundance within this genus), followed by *Mycoplasma bovirhinis* (4.5%). The Proteobacteria phylum was comprised mostly of *Pasteurella* (32.4%), *Ralstonia* (29.5%), *Moraxella* (26.2%) and a smaller percentage of *Mannheimia* (2.3%).

A distinct shift in the community profile was apparent among time points (i.e. weaning, on arrival at a feedlot, and 40 d after arrival). In total, 92 OTUs changed over time, as identified using a generalized linear model approach. With regards to α -diversity measures, there was no difference among time points in the number of observed OTUs ($p = 0.87$) and Shannon diversity ($p = 0.10$).

Conclusions: (i) The nasopharyngeal microbiota of cattle underwent a rapid and profound evolution from weaning to arrival at the feedlot and during the first 40 days at the feedlot; and (ii) *M. dispar* and *M. bovirhinis* dominated the nasopharyngeal microbiota of healthy cattle. Because an evolving bacterial community may be less capable of resisting colonization by pathogenic bacteria, the instability of the nasopharyngeal microbiota documented in this study might explain why cattle are most likely to be affected with BRDc during the first weeks after weaning.

¹UMR 1300 ONIRIS - INRA BIOEPAR, Nantes, ²Qalian, InVivo Animal Nutrition and health, Segré, France

Objectives: Formaldehyde and CuSO₄ have been used in footbaths as the standard treatments of bovine digital dermatitis (BDD). Others several collective treatments (CT) are commercialized, frequently without evidence of their effectiveness. The objective of this exhaustive review was to scrutinize the clinical evidence that support collective treatments in the control of BDD. For each study, preventive and curative outcomes were expressed through numbers needed to treat (NNT) an original, easy and useful measure of the treatment benefit, which represents the number of animals that must be treated to make a positive or negative difference on one animal.

Materials and Methods: Clinical evidence was collected across an evidentiary search strategy that included electronic data-bases, 375 citations were screened for relevance by the authors and 15 references were selected. Additionally, a manual search of the grey literature was performed, and 8 additional relevant reports were identified. Altogether, 23 relevant reports were included to be verified by the authors through a screening tool specifically designed for this review. Finally 15 studies were included, excluding trials with missing information and limiting the evidence to (i) trials conducted in dairy cattle herds (ii) where the disease occurred naturally and (iii) that compared CT to a negative control or placebo group. Two outcomes were differentiated. The therapeutic outcome was defined as the positive effect measured by reduction on the persistence and recurrence of BDD lesions. The preventive outcome was defined as the positive effect of the intervention to limit the occurrence of a new BDD lesion. First, the outcomes were summarized and the absolute risk reduction (ARR) was calculated by the difference in percentage of clinical success between the treated and the negative control or placebo group. The NNT statistics were obtained by dividing, the ARR into 100%. The small number of studies included was due mostly to the absence of comparative negative controls in the study protocols, the missing information and the absence of significant results (5 of 15).

Results: For the curative outcome, the few treatments that were reported as significantly effective ($P < 0,05$) were, (i) Oxytetracycline (25mg/ml) sprayed 8 times in hoofs prerinsed with water once daily, 5 consecutive days, no treated for 2 days, and then treated 3 times every other day (NNT=2); (ii) Commercial formulation of soluble copper, peroxide compound, and a cationic agent sprayed 8 times in hoofs prerinsed with water once daily, 5 consecutive days, no treated 2 days, and then treated 3 times every other day (NNT=2); (iii) Acidified ionized copper (0.6%) in footbaths administered 5 times, twice daily for periods of 10 days aprox. the product was renewed each 300 passages (NNT=3); (iv) Water prerinse footbath+CuSO₄ pentahydrate (25%) in footbaths administered after 4 consecutive milkings every week during 5 weeks, the product was renewed each 200 passages (NNT=4); (v) Foam tensides and peracetic acid system administered twice a day on alternate weeks during 8 weeks (NNT=5); (vi) Tap water mixed with soap solution (0.4%) administered through an automatic hoof washer twice a day during 8 weeks (NNT=12).

For the preventive outcome the treatments that were reported as significantly effective ($P < 0,05$) were (i) Cooper and zinc chelates (50%) sprayed in hoofs prerinsed with water after 2 milkings 4 days apart every 2 weeks during 6 months (NNT=15); (ii) Cooper and zinc chelates (5%) in footbaths administered to hoofs prerinsed with water after 4 consecutive

milking every 2 weeks during 6 months, the product was renewed each 150 passages (NNT=25).

Conclusions: As a consequence, this review reveals that there is weak scientific evidence supporting the preventive or therapeutic effectiveness of collective treatments against BDD, explained mostly by the high particularities of the treatment protocols and populations that make difficult extrapolate the results to other populations. These findings support the importance to develop uniform protocols including negative controls for trials evaluating the effectiveness of collective treatments.

Comments: The NNT can only be compared within the same trial because it represent the effect of a treatment compared to a control or placebo group under the specific conditions of the study, indicating the spontaneous cure rate and the severity of the disease challenge into a specific diseased population.

The comparison of the collective treatments effectiveness on the control of BDD is complicated by multiple causes. Firstly, a high recurrence of the disease after an initial clinical resolution, and a variable rate of spontaneous cure, even up to 60%. Finally, there are important differences across populations and trials protocols and also in terms of NNT animals among effective treatments (varying from 2 to 25).

Prevalence and Discovery of Genetic Defects in the National Irish Cattle Population

Jennifer McClure ^{1,*} Paul Flynn ² Michael P. Mullen ³ Thierry Pabiou ¹ Robert D. Schnabel ⁴ Jeremy F. Taylor ⁴ Sinead Waters ⁵ Rebecca Weld ² Matthew McClure ¹

¹Irish Cattle Breeding Federation, Bandon, ²Weatherbys, Johnstown, ³Department of Life and Physical Sciences, Athlone Institute of Technology, Athlone, Ireland, ⁴Division of Animal Sciences, University of Missouri, Columbia, United States, ⁵Animal & Grassland Research and Innovation Centre, Teagasc, Athenry, Ireland

Objectives: Genetic diseases occur in every cattle breed worldwide. Genetically superior animals can be carriers for known genetic defects; therefore, screening and strategic mating is the best method to control disease frequency. Methods to identify genes of interest in animals where a causative mutation has not been found must be utilized to maximize the genetic potential of cattle. This study endeavoured to do both in the Irish national cattle population using genotyping with the International Dairy and Beef (IDB) SNP chip to determine carrier status for 38 mutations and through exome sequencing to identify punitive mutations for progressive ataxia.

Materials and Methods: Genetic Disease Frequency: DNA from independently confirmed carrier or affected animals was used to validate the diagnostic ability of 65 disease and trait SNP probes on the International Dairy and Beef (IDB) SNP chip. Since 2013, 170,992 Irish animals have been IDB genotyped and allele frequencies from the validated disease probes were analysed to calculate carrier frequencies for 38 mutations that are causative for 33 different diseases. Some genes have multiple mutations that result in the same disease phenotype. This provides a snapshot of the prevalence of the 38 disease-causing alleles across multiple breeds, for pedigree and commercial animals, and for AI and stock bulls.

Genetic Disease Causative Mutation Discovery: A genetic disease in Charolais cattle, Progressive Ataxia, was farmer identified, veterinarian confirmed, and reported to ICBF. Pedigree analysis of affected animals supported an autosomal recessive disease model. Tissue from two affected paternal half-sib animals and their parents were collected, DNA was extracted, and IDB genotyped. Genotypes were analysed using SNP & Variation Suite v8x (Golden Helix, Inc., Bozeman, MT) to identify extended runs of homozygosity (ROH) that were unique to the affected animals. DNA from affected animals was sent to CoFactor Genomics for Exome sequencing. Exome sequence variants were compared to a reference population of 244 whole genome sequenced *Bos taurus* individuals to identify variants that were unique and homozygous in the affected animals and were within the ROH.

Results: Disease Mutation Allele Frequencies: Of the 38 disease-causing mutations, 27 are segregating in the Irish national beef and dairy herd. While the national dairy herd is primarily Holstein-Friesian the beef herd is a composite of multiple breeds, purebreds, and crossbred animals. Typically, the frequency of a disease mutation is determined via genotype data from the pedigree and AI population. This study's data set provides a rare insight into allele frequency differences between a country's commercial and pedigree herds. Most of the disease-causing alleles are at a higher frequency in the commercial than the pedigree herd, and are also higher in frequency in stock than AI bulls. Of concern, some of the mutations that require payment of a separate royalty fee for genotyping including: Brachyspina, Complex Vertebral Malformation, and Tibial Hemimelia-Improver have carrier rates >3% within at least one breed.

Progressive Ataxia Putative Causative Mutations: Through Exome sequence analysis 8 SNP were identified as candidate causative

mutations, however, through further examination of the literature it has been deemed possible that the causal mutation may lie in a genomic region that is not covered by exome sequencing. These SNP were included in the design of the IDBV3 and their allele frequencies in the national herd and genotype status of affected animals will be used to identify if any of the exome-sequencing detected SNP are the causal mutation.

Conclusions: Through the identification of carrier animals in a population, better mating strategies can be implemented to reduce the chance of producing animals affected by genetic diseases when causative mutations are known. Ireland began this process with the development of the IDB chip and will continue to add new disease-causing SNPs as they are published. While exome sequencing produced 8 candidate casual mutations for progressive ataxia, the data will be strengthened by whole genome sequencing of the affected animals, and future validation studies. This method will then be used to identify the variants causing new genetic diseases as they appear.

GB-047-002

Estimation of genetic parameters of postpartum health disorders in Holstein cows

Vangelis Tsiamadis ^{1,*} Nikolaos Panousis ² Georgios Banos ¹ Maria Kritsepi-Konstantinou ³ Georgios Arsenos ¹ Georgios E. Valergakis ¹

¹Laboratory of Animal Husbandry, ²Farm Animal Clinic, ³Diagnostic Laboratory, Faculty of Veterinary Medicine, School of Health Sciences, Aristotle University of Thessaloniki, Thessaloniki, Greece

Objectives: The objective was to estimate the genetic parameters of: a) serum Ca, Mg, P, K and β -hydroxybutyric acid (BHBA) concentrations; b) the associated subclinical macromineral disorders, and c) clinical diseases of dairy cows during the first 8 days after calving.

Materials and Methods: The study included 1,021 Holstein dairy cows (1 - 4+ lactations) in 9 herds. No herd used preventive measures for hypocalcemia. Clinical examination and blood sampling was performed on DIM 1, 2, 4 and 8. Clinical cases of milk fever (MF), retained fetal membranes (RFM), metritis (MET), mastitis (MAST), left/right abomasal displacement (LDA/RDA), ketosis (KET), and uterine prolapse (UP) were recorded on the same days. Serum concentrations of Ca and Mg were determined with AAS, while P and K with biochemical and electrolyte analyzers. BHBA was measured with a spectrophotometer in samples of day 8. The final data set included 4,020 Ca, 4,019 P, 4,020 Mg, 3,792 K, 997 BHBA measurements and 4,064 clinical records. All pedigree available was included in the analysis bringing the total number of animals to 4,262. Macromineral-related traits defined as: subclinical hypocalcemia (SCHCa): Ca \leq 8.3 mg/dL; hypophosphatemia (HypoP): P \leq 4.2 mg/dL; subclinical hypomagnesemia (SCHMg): Mg \leq 1.8 mg/dL; hypokalemia (HypoK): K \leq 3.9 mEq/L; and hyperphosphatemia (HyperP): P \geq 7.80 mg/dL. Macromineral and clinical disease-related traits were analyzed with a univariate random regression model. A similar single record model was used for the analysis of BHBA concentration. Genetic correlations among all the above traits were also estimated with a series of bivariate analyses. The genetic analysis for Ca, Mg, P and K and the associated health traits included 986 cows, which showed no obvious signs of MF (35 cows with MF were excluded). The analysis for the other health traits included all 1,021 cows.

Results: Mean serum Ca, P, Mg K and BHBA concentration (\pm s.e.m.) was 8.92 \pm 0.018 mg/dL, 5.21 \pm 0.020 mg/dL, 2.24 \pm 0.006 mg/dL, 4.58 \pm 0.009 mmol/L, 829.03 \pm 602.29 μ mol/L, respectively. Daily heritabilities of Ca

(0.23 - 0.32), P (0.30 - 0.43) and Mg (0.20 - 0.39) were moderate to high, while those of K were low to moderate (0.12 - 0.23). Heritability of BHBA concentration was 0.19±0.09. Daily heritabilities of SCHCa (0.13 - 0.25), HypoP (0.18 - 0.33), SCHMg (0.11 - 0.38) and HyperP (0.14 - 0.22) were low to moderate, while that of HypoK was low (0.08 - 0.10). All these estimates were statistically greater than zero ($P < 0.05$). Statistically significant daily heritabilities ($P < 0.05$) of postpartum health diseases were those of MF (0.07 - 0.11), MAST (0.15 - 0.41) and LDA (0.19 - 0.31). No significant genetic correlations among biochemical traits and clinical or subclinical health traits were found.

Conclusions: Serum concentrations of Ca, P, Mg, K and BHBA, as well as SCHCa, HypoP, HyperP, SCHMg, HypoK, MF, MAST and LDA during the first 8 days after calving are heritable traits in Holstein cows. Genetic selection could contribute to minimize the incidence of these disorders.

GB-047-003

A stop-gain in the laminin, alpha 3 gene causes recessive junctional epidermolysis bullosa in Belgian Bleu cattle

Arnaud Sartelet ^{1,*}, Chad Harland ², Nico Tamma ³, Latifa Karim ⁴, Calixte Bayrou ⁵, Wanbo Li ², Naima Ahariz ⁴, Wouter Coppieters ⁴, Michel Georges ², Carole Charlier ²

¹Clinical Department of Production Animals & FARA, ²Unit of Animal Genomics, GIGA-R and Faculty of Veterinary Medicine, University of Liège, ³Unit of Animal Genomics, GIGA-R and Faculty of Veterinary Medicine, University de Liège, ⁴GIGA-Genomic platform, ⁵Department of Pathology, FARA and Faculty of Veterinary Medicine, University of Liège, Liège, Belgium

Objectives: Intensive selection for desired production traits, exacerbated by the extensive use of artificial insemination, drastically reduces the effective population size of livestock populations including cattle. This leads to frequent outbursts of genetic defects, which are causing major economic and welfare concerns. We have established a heredo-surveillance platform in the Belgian Blue Cattle breed (BBCB) highly selected for meat production to (i) monitor the emergence of novel genetic defects, (ii) identify causative loci and mutations by positional cloning, (iii) develop and offer indirect and direct diagnostic tests.

Materials and Methods: Four newborn purebred Belgian Blue calves presenting a severe form of epidermolysis bullosa were recently referred to our heredo-surveillance platform. SNP array genotyping followed by autozygosity mapping located the causative gene in a 8.3-Mb interval on bovine chromosome 24. Combining information from (i) whole-genome sequencing of an affected calf, (ii) transcriptomic data from a panel of tissues and (iii) a list of functionally ranked positional candidates pinpointed a private G to A nucleotide substitution in the Laminin, alpha 3 (LAMA3) gene that creates a premature stop codon (p.Arg2609*) in exon 60, truncating 22% of the corresponding protein.

Results: The LAMA3 gene encodes the alpha 3 subunit of the heterotrimeric laminin-332, a key constituent of the lamina lucida that is part of the skin basement membrane connecting epidermis and dermis layers. Homozygous loss-of-function mutations in this gene are known to cause severe junctional epidermolysis bullosa in human, mice, horse, sheep and dog. Overall, our data strongly support the causality of the identified gene and mutation. We developed a TaqMan-based direct diagnostic test to interrogate the c.7825C>T mutation. The four cases were confirmed homozygous mutant, and a carrier frequency of ~1% was estimated within the BBCB by screening a cohort of 3,000 animals.

Conclusions: Jointly with all previously identified deleterious and functional mutations in BBCB, direct genotyping of this new variant is now routinely applied on a low-density custom array to avoid carrier-carrier matings in breeding schemes. This study confirms the power of state-of-the-art genomic tools to rapidly elucidate the molecular basis of emerging monogenic disorders in livestock.

GB-047-004

Conserved DNA elements may influence expression of reproduction-associated bovine beta-defensins

Anne Barry-Reidy ^{1,*}, Karsten Hokamp ², Kieran G. Meade ³, Cliona O'Farrelly ¹

¹School of Biochemistry & Immunology, ²Smurfit Institute of Genetics, Trinity College Dublin, Dublin, ³Animal & Grassland Research and Innovation Centre, Teagasc, Co. Meath, Ireland

Objectives: β -defensins are an important class of host defence peptides (HDPs). A growing body of evidence has implicated these genes in the fertility of several species, particularly a syntenic cluster which is predominantly or solely expressed in the male reproductive tract. Having been the first to confirm the existence of these genes in the bovine genome, we are interested in elucidating their role in reproductive function and fertility. As the mechanisms regulating these pleiotropic molecules are poorly understood, we aimed to bioinformatically analyse this gene region to identify probable regulatory elements and stimuli driving transcription.

Materials and Methods: Our comparative genomics approach centred on the identification of conserved non-coding regions in the β -defensin gene cluster across multiple species. Gene regulation at the transcription level is mediated by transcription factors which participate in chromatin modelling and bind DNA to enhance or repress transcription. These proteins recognise short DNA motifs of specific sequence which can be found in gene-proximal promoter regions or in distal enhancers, meaning such functional DNA elements are highly conserved. 5kb promoter regions from a minimum of 8 mammalian orthologs of each β -defensin gene were analysed using oPOSSUM3 software for transcription factor binding sites which were over-represented compared to a length- and GC-matched background dataset of randomly-selected human gene promoters. 300kb of the β -defensin gene region from 5 species separated by over 80MYA of evolution was aligned using a threaded-blockset approach. Following commonly-used criteria, a DNA sequence conservation cut-off of 70% over 100bp is the minimum required to identify an evolutionarily-conserved region (ECR). A more stringent cut-off of 77% over at least 350bp is thought to be indicative of a core enhancer with increased importance. These DNA regions were analysed using a web-based tool called CLARE which builds a predictive model of features common to the input set versus a sequence-scrambled background set of DNA sequences.

Results: DNA binding sites for several transcription factors are statistically overrepresented in the 5'UTR promoters of β -defensin genes versus a control background gene set. These include androgen receptor, glucocorticoid receptor, retinoic acid receptor, PAX5 and RFX1. These transcription factors are all expressed in the testis and several have been shown to be important in regulating spermatogenesis. The β -defensin gene region contains basic ECRs located in immediate 5' and 3' regions, intronic and intergenic regions. Three putative core enhancers were identified in silico. An enhancer located within a subset of β -defensins solely expressed in the reproductive tract of the sexually mature male contains binding sites for androgen receptor and AP-2 α , a chromatin-

opening transcription factor known to co-operate with androgen receptor in the murine epididymis. A second enhancer contains binding sites for GATA1 and RFX1, which have also been implicated in spermatogenesis.

Conclusions: A comparative genomics approach is a powerful first step toward understanding evolutionarily conserved regulatory mechanisms for these multifunctional genes. The signature of over-represented transcription factors agrees with the observed expression pattern of these genes. Identified intergenic ECRs may act as distal regulatory elements to control expression of one or several male reproductive tract-specific β -defensins in tandem. These regulatory elements will be targets of experimental assays to determine their contribution to transcriptional regulation of β -defensin genes and bovine fertility.

herds with two and three breed animals increased from 1% in 1990 to 17% in 2013. Very few three-breed crossbreeding herds were identified.

Conclusions: Of the farms in Australia which are regularly milk-recording, the most common breed structures are the single breed purebred herd and the "less serious" 2-breed crossbred herd, with both comprising around one-third of herds in recent years. These results show that a substantial proportion of Australian dairy herds contain some crossbreds but few have used cross-breeding on an ongoing systematic herd-wide basis. Further research will describe these breed patterns in more detail. As some herds may benefit from crossbreeding, further studies are required to better understand farmer beliefs about, and experiences of, crossbreeding.

GB-047-005

The use of crossbreeding in Australian dairy herds

Jo Coombe^{1,2,*}, Michael Pyman¹, John Morton³, David Beggs¹

¹Faculty of Veterinary and Agricultural Sciences, University of Melbourne, ²Dairy Australia, Melbourne, ³Jemora Pty LTD, Geelong, Australia

Objectives: The objective of this study was to describe herd breed structures over time for a large subset of Australian dairy herds. The main area of interest for this study was the use of crossbreeding by dairy farmers; specifically proportions of farms using crossbreeding, and whether they were using 2-breed or 3-breed systems.

Materials and Methods: The study was a retrospective descriptive study. Data was from milk-recording herds extracted from the Australian Herd Improvement Scheme (ADHIS) database. The unit of interest was the herd-year. Breed categories for herd-years were defined as: 1) purebred herds: further divided into a) single breed herds: a herd-year where >95% of calvings were to purebred cows, $\leq 1\%$ of the calvings were to F1 cows, and only one purebred had >5% of calvings b) dual breed herds: as above but two purebreds had >5% calvings each, c) purebred herd with more than 2 breeds: as above but more than two purebreds had >5% calvings each, and d) purebred herd containing a few crossbreds: a purebred herd (>95% of calvings were to purebred cows) but >1% of calvings were to F1 cows); 2) two-breed crossbreeding herds: further divided into "more serious" or "less serious": "more serious": >50% of calvings by 2 year-old cows were F1 (e.g. JJFF) or backcross (e.g. FFJF or JJJF); "less serious": >0% and $\leq 50\%$ were F1 or backcross; 3) three-breed crossbreeding herds: >50% of calvings by 2 year-old cows were to a 3-breed backcross and none were to a 2-breed cross; 4) crossbreeding herd with two and three breed animals: (of the calvings by 2 year-old cows in that herd-year, at least 1 was to a 2-breed and at least 1 was to a 3-breed animal); 5) non-purebred herd with all purebred 2 year-olds: a herd in which $\leq 95\%$ of the calvings in the herd were to purebreds, but all 2 year-old cows that calved were purebred.

Results: Within each herd, each calendar year (ie each herd-year) from 1990 to 2013 with sufficient data was categorised. The most common herd breed categories were single breed purebred herds (38% of all herd-years; 33% to 38% of herds in each year from 2010 to 2013) and "less serious" two-breed crossbreeding herds (35% of all herd-years; 33% to 36% of herds in each year from 2010 to 2013). Dual breed purebred herds were rare (1% of all herd-years), as were "serious" two-breed crossbreeding herds, (although the proportion of herds that were this category increased slightly from 1% of herds in 1990 to 5% in 2013). The proportion of herds that were purebred herds containing a few crossbreds fell from 23% in 1990 to 6% by 2013, while crossbreeding

IV-027-001

Associations between immune competence, stress responsiveness and production in Australian Holstein-Friesian heifers

Josh Aleri ^{1,*}, Brad C. Hine ², Michael Pyman ¹, Peter Mansell ¹, Bill Wales ³, Bonnie Mallard ⁴, Andrew D. Fisher ¹

¹Faculty of Veterinary and Agricultural Sciences, University of Melbourne, Werribee, ²Agriculture Flagship, CSIRO, Armidale, NSW, ³Agriculture Research and Development Division, Department of Economic Development, Jobs, Transport and resources, Ellinbank, Victoria, Australia, ⁴Department of Pathobiology, Ontario Veterinary College, University of Guelph, Ontario, Canada

Objectives: The objectives of this study were to assess and classify adaptive immune responsiveness in first lactation Holstein-Friesian heifers reared under a pasture-based production system and to determine relationships with stress responsiveness, resistance to internal parasites, udder health and production performance. Furthermore, immune responsiveness in purebred Holstein-Friesians and crossbred Holstein-Friesians were investigated.

Materials and Methods: A commercial vaccine was used to induce measurable antibody and cell-mediated immune responses, and animals were classified as High, Medium and Low responders for antibody (AMIR), cell-mediated (CMIR) and combined immune response (CIR). Short-term handling and yarding effects measured stress responsiveness, fecal egg count measured resistance to internal parasites, somatic cell counts assessed udder health and production performance was assessed using estimates of total daily milk volume, milk fat and milk protein. A total of 403 pre-joining heifers from two herds in a seasonally calving, pasture-fed production system were enrolled in the study and followed to the end of their first lactation cycle.

Results: Tests for correlations between stress and immune responses showed a negative correlation with AMIR and a trend towards positive correlation with CMIR ($R=0.068$). The crossbred-bred Holstein-Friesians recorded a higher AMIR compared to the pure bred Holstein-Friesians, and there were no differences in CMIR. Fecal egg counts were generally low and the assessment for resistance to internal parasites showed no significant correlations. Linear individual cow somatic cell scores of 2.39 - 2.68 were recorded within the lactation cycle with significant differences between the early and late lactation period. No significant differences were recorded between the immune response groups in the linear cell counts and milk yield. A negative correlation was observed between milk yield and the magnitude of AMIR whereas a positive correlation was observed with the intensity of CMIR. A significant difference was recorded in fat content in the AMIR group with high responders recording higher 305 day fat yields compared with their low responder counterparts. No significant difference was observed for the CMIR and CIR groups. No significant differences were observed in protein content between the immune response groups.

Conclusions: From this study, it is concluded that stress and AMIR were negatively correlated and immune responses were variable within the breeds. The high-AMIR responders had better milk quality compared with other immune responders and no relationships were observed between SCC and resistance to internal parasites with immune responsiveness.

IV-027-002

Influence Of Maternal Antibodies On Induction Of Vaccine Immune Response Against Respiratory Viruses In Holstein Calves

Bruno T. Silva ¹, Camila C. Baccili ¹, Sylvania M. F. Novo ¹, Juliana F. D. Reis ¹, Natália M. Sobreira ², Edviges M. Pituco ³, Viviani Gomes ^{1,4,*}

¹Internal Medicine, University of São Paulo, São Paulo, ²Colorado Farm, Araras, ³Bovine Virus Laboratory, Biological Institute, ⁴University of São Paulo, São Paulo, Brazil

Objectives: The interface between passive and active immunity in calves may represent the main risk factor for bronchopneumonia, since the decay of maternal antibodies (Abs) encourage the infection by respiratory viruses. The remaining Abs, even if not protect the newborns, could exert a suppressive effect on the development of humoral immunity induced by vaccination. Thus, the hypothesis is that circulating maternal Abs blocks the vaccinal response. The purpose of this research was to evaluate the influence of maternal Abs on vaccine immune response to viruses involved in Bovine Respiratory Disease (BRD) in calves with 14, 90 and 180 days of age.

Materials and Methods: The newborns received 4L of colostrum in the first 12 hours of life, obtained from colostrum donor cows vaccinated with Cattle Master Gold FP5+L5® (Zoetis, Brazil), composed by inactivated strains of BVDV type 1 (5960) and type 2 (53637); live/thermosensitive BoHV-1 (Cooper) and BPIV-3 (RLB 103); live/attenuated BRSV (375) and Leptospira. The animals were randomly distributed into four groups: G1 - vaccinated at 14d and booster at 44d (n=6); G2 - at 90d and booster at 120d (n=5); G3 - at 180d and booster at 210d (n=8). Control group (CG, n=5) non-vaccinated also was evaluated from birth up to 240 days of life. Blood samples were harvested at vaccination (T0), booster (T1) and 30 days after second dose (T2).

Results: The vaccine did not promote increase in Abs titer (Log₂) for BVDV in any of the groups. Calves from G1 presented titers for BVDV of 12.3 (10.3-12.3) at T0 and 8.8 (7.3-11.3) at T2; the G2 showed titers of 7.3 (4.3-8.3) at T0 and 6.8 (3.3-7.3) at T2, and G3 titers of 5.3 (0.0-6.3) at T0 and 7.3 (0.0-10.3) at T2. Same values could be observed in the control groups at all moments. The Abs titer to BoHV-1 observed in G1 were of 6.5 (6.0-7.0) at T0 and 6.0 (5.0-8.0) at T2; in G2 of 4.5 (0.0-6.0) at T0 and 4.0 (0.0-10.5) at T2 and G3 of 7.5 (0.0-10.0) at T0 and 10.0 (0.0-10.0) at T2. Differences could be demonstrated only between G3-CG3 ($P=0.01$). BRSV presented different profile with Abs titers of 3.5 (0.0-4.0) at T0 and 3.5 (0.0-4.0) at T2 in G1, of 0.0 (0.0-3.0) at T0 and 0.0 (0.0-3.0) at T2 in G2, and of 5.0 (3.0-10.0) at T0 and 8.5 (4.0-10.0) at T2 in G3. Similar values could be found for the CG, except at T0 ($P=0.04$) with high titers for CG3 (0.0-7.0), and at T2 ($P=0.01$) with low titers for CG3 (0.0-4.0). For BPIV-3, the Abs titer for G1 were of 8.0 (7.0-10.0) at T0 and 5.5 (3.0-9.0) at T2, for G2 were of 4.5 (0.0-5.0) at T0 and 5.0 (0.0-5.0) at T2 and for G3 were of 5.0 (0.0-10.0) at T0 and 10.0 (0.0-10.0) at T2. Differences could be detected between CG at T0 ($P=0.02$), demonstrating high titers for CG2 (4.0-7.0), and at T2 ($P=0.05$) with low titers for CG3 (0.0-5.0). No differences among moments were observed ($P<0.0167$) for any of the viruses. The susceptibility for bronchopneumonia could be demonstrated from 90-120d, since 4/5 (80%) calves were sick in non-vaccinated group.

Conclusions: Maternal immunity and vaccine response presented inverse relationship. Thus, the early vaccination in the G1 did not promote increase in Abs titer for any of the viruses, while the vaccination at 90 days of life (G2) and 180d (G3) improved the Abs response after booster due to the decay of maternal Abs at these ages.

IV-027-003

Switch your energy supplier – and treat less infectious diseases.Dirk Werling ^{1,*}¹Pathology and Pathogen Biology, Royal Veterinary College, Hatfield, United Kingdom

Objectives: One of the truly remarkable discoveries in modern biology is the finding that the nervous system, endocrine system and immune system use a common chemical language for intra- and inter-system communication. This has severe consequences, especially in such times where a situation of high-energy expenditure exists in a host, which becomes aggravated through the fact that the host has to mount an additional immune response

Materials and Methods: Here, I will summarise our current understanding regarding the energy consumption to mount an immune response, and will discuss the potential consequences in light of physiological occurring times of high energy expenditure, especially during the peri-parturient period. Indeed, during this period it may be beneficial to the host to spend energy on prophylaxis, rather than treatment. Here, treatment using immunomodulators, naturally occurring proteins of the immune system, may provide a new way forward.

Results: Indeed, immunomodulators, such as granulocyte-colony stimulating factor have been tried in various experimental approaches for treatment of infectious diseases in humans and farm-animals. However, only recently have these immunomodulators been produced in a form that makes their usage substantially more appropriate for treatment, of certain cancer forms in humans. However, it seems that the use of similar, "own" molecules with a modification that increases their half-life may also aid and/or prevent the occurrence of economically important infectious diseases in animals.

Conclusions: The use of proteins produced by the host itself in a recombinant form may provide a new ways forward to tackle old problems by prevention rather than treatment of infectious diseases in a time when the over-use of antibiotics has led to an increase in multi-drug resistant bacteria as well as an increased consumer awareness of the value of food products.

Such a shift from re-active energy expenditure to a prophylactic, active energy expenditure may prevent energy losses in the long term, leading to a faster restoration to homeostasis and therefore an overall increase in overall animal welfare.

IV-027-004

Passive Immunity In Calves Stimulated By Vaccination Of Dry Cows For SalmonellaGeof Smith ^{1,*}, Derek Foster ¹¹Population Health and Pathobiology, North Carolina State University, Raleigh, United States

Objectives: Salmonella infections are an economically important disease of cattle and also represent a worldwide public health concern. Although cattle of all ages can be infected with Salmonella bacteria, death is most often reported in calves less than 8 weeks of age. The goal of this research was to determine whether vaccinating cows at dry off with commercially available Salmonella vaccines would result in the

presence of Salmonella specific IgG antibodies in the colostrum of cows at calving and whether these colostral antibodies would be transferred to the calf.

Materials and Methods: Two different prospective clinical trials were conducted using 2 different commercially available Salmonella vaccines. In one study, 30 Holstein cattle from a dairy herd naïve to Salmonella were vaccinated at dry-off with a Salmonella enterica serovar Newport bacterin and again 4 weeks later. An additional 30 cows received only saline and served as an unvaccinated control group. In a separate trial 30 Holstein cows were vaccinated 3 weeks before the end of lactation with a Salmonella enterica serovar Dublin vaccine with a second dose given at dry-off. Once again an additional 30 cows received only saline and served as a control group. Calves from both studies received fresh colostrum from their dam within 2 hours of birth, and had blood collected 24 hours later. Serum and colostral antibody titers for S. Newport or S. Dublin antibody concentrations were determined using enzyme-linked immunosorbant assays (ELISA).

Results: Cattle vaccinated with the S. Newport bacterin had elevated S. Newport antibody titers at calving in blood (P = 0.01) and colostrum (P = 0.011). Calves that received colostrum from vaccinated cattle also had significant increases in Salmonella antibody titers (1.04 + 0.03 presented as S/P ratio) as compared to calves born to unvaccinated cows (0.30 + 0.02). Cattle vaccinated with the Salmonella Dublin vaccine had elevated S. Dublin antibody titers at the time of calving (40.3 + 9.1 presented as percent positivity) as compared to control cows (-9.4 + 1.1). Calves that received colostrum from vaccinated cattle also had a significant increase in S. Dublin antibodies (88.5 + 8.9) as compared to calves born to unvaccinated cows (-3.2 + 1.2).

Conclusions: The results of these clinical trials indicate that the use of commercially available Salmonella vaccines can stimulate antibodies that are passed on to the calf via colostral transfer. Ongoing research is being conducted to determine whether these colostral antibodies will offer protection against Salmonella challenge. However vaccination of the dam during late gestation may provide some immunity to young calves when Salmonella challenge occurs within the first few weeks of life. The use of dry cow vaccination to provide colostral antibodies offers a way to provide some degree of protection until calves are old enough to be vaccinated.

IV-027-005

Cobalt Supplementation Affects Humoral Immune Response In Beef CalvesBob Sager ^{1,*}¹Miratorg Holdings Bryansk, Russia, Miratorg Holdings PLuskova Farm Pluskova, Russia, Russian Federation

Objectives: The objective of this study was to evaluate if a sustained release cobalt (30 gm Co O4) bolus dosed pre-weaning affects the humoral immune system post weaning and improves health during the feeding period in the feedlot.

Materials and Methods: Five different ranches with similar genetics, same forage base, mineral, same water aquifer base, and same preweaning health program were utilized in this study. Two hundred, six to eight month old steer calves (BW 220+/- 24 kg) were randomly selected from over 2000 head. One hundred steers were randomly selected to receive a sustained CoO4 bolus at vaccination and one hundred were selected as controls. All calves were vaccinated for Mannheimia haemolytica three weeks before weaning and were bled for

existing Mannheimia haemolytica leukotoxin antibody titers at the time of treatment. All calves were weaned and transported the same day to a feedlot in Minnesota. Calves were rebled at d 70 in the feedlot. All calves in the study received the same mineral and feed rations during the feeding period and were harvested on the same day. Differences between treatment and control groups were analyzed by a Welch Two Sample t test with differences significant at $P < 0.05$.

Results: Differences between treatment and control calves showed treatment calves had an increase of 42% in Mannheimia haemolytica leukotoxin antibody ($P < 0.0586$) compared to control calves. Feedlot health (morbidity and mortality) was evaluated before weaning and during the feedlot period. Differences between treatment and control groups during the feeding period showed decreased BRD in the treatment group ($P < 0.0217$) compared with the control group. Final carcass data showed no differences in Yield nor Grade but did show an increase in HCW of 17.81 kg in the treatment group. This resulted in an increase of \$97.81 per treatment carcass after cost of treatment compared to the control group.

Conclusions: Results by this study show that supplemented Co at preweaning has potential to increase humoral immune response, decrease BRD during the feeding period, and increase profits at harvest. The sustained Co O 4 bolus supplied approximately 20 ppm of Co daily in the ration which is approximately twice NRC recommendations. Further studies need to be completed to indicate desired recommended levels.

IV-027-006

There is a need to raise farmers' awareness of correct vaccine storage temperatures

Paul Williams¹,*G. Paixao²

¹MSD Animal Health, Milton Keynes, ²University of Bristol, Bristol, United Kingdom

Objectives: According to label requirements vaccines are often stored on farm in a fridge (2 and 80C) prior to being administered. Failure to maintain correct storage temperature has been shown to compromise vaccine efficacy and indirectly, animal health. Live vaccines are more sensitive to potency loss at elevated temperatures. Inactivated vaccines are typically more stable to moderate heat exposure, but more sensitive to freezing. The aim of this study was to monitor the temperature of farm fridges used to store both live and inactivated animal vaccines.

Materials and Methods: Between January and August 2014, temperature data loggers (EL-USB-2-LCD, Lascar Electronics, UK) were placed on 19 farms in south-west England. On each farm 3 data loggers were placed, 2 inside the farm fridge used to store vaccines and 1 in the room in which the fridge was situated. The loggers were set to record the temperature every 30 minutes. Data logger temperature recordings were analysed using Microsoft Excel 2010 (Microsoft Corporation). For each data logger, individual temperature recordings below 20C or above 80C were identified. The recordings for each data logger were further categorised into "Events". An Event occurred when 2 or more consecutive individual recordings were below (or above) a defined ($>80C$, $<20C$ and $=$ or $< 00C$) temperature parameter. For each Event, the minimum (or maximum) temperature was recorded, as well as the duration.

Results: Of the 19 farms, complete data for analysis were available from the fridges on 17 farms (8 dairy, 2 pig, 4 sheep and 3 beef/sheep). None of the fridges maintained the internal temperature between 2 and 80C during the study period. Sixteen fridges had at least 1 individual fridge temperature recording above 80C, the maximum fridge temperature

recorded being 240C. There was an increase in the number of fridges with a recording above 80C between May to August, suggesting an impact of higher environmental temperature. Of these 16 fridges, 14 had at least one Event, where the fridge temperature was sustained above 80C for at least 30 minutes. Eleven fridges had at least 1 individual temperature at or below 00C, the minimum fridge temperature recorded being -120C. The number of fridges with a recording at or below 00C did not alter on a monthly basis during the study. Of these 11 fridges, 7 had at least one Event where the temperature was sustained at or below 00C for at least 30 minutes, providing an opportunity any vaccine vial contents to become frozen.

Conclusions: All of the fridges in this study failed to maintain the temperature range required to store vaccines correctly. In a significant number of fridges, the temperature was outside the required storage range for a long enough period of time to produce a loss of vaccine potency. This may have a negative impact on both vaccine efficacy and animal health. There is a need to increase awareness amongst farmers of correct vaccine storage temperatures. This could be achieved with on-going monitoring to ensure this is complied with.

IV-027-007

Intranasal Vaccination in the Face of Maternal Antibody Induces Long-term Mucosal Immune Memory

Kevin L. Hill¹,*Philip J. Griebel²

¹Merck Animal Health, Desoto, United States, ²VIDO/Intervac, Saskatoon, Canada

Objectives: Intranasal (IN) vaccination of newborn calves with a modified-live viral (MLV) vaccine is an effective strategy to avoid vaccine interference by maternal antibody and induce mucosal immunity with local production of IgA (Hill et al. 2012). The objective of the present study was to determine if vaccination of young calves, in the face of specific maternal antibody (IFOMA), with an IN MLV bovine herpesvirus-1 (BHV-1) and parainfluenza virus-3 (PI-3) vaccine would induce protective immune memory, compared to a MLV and a killed viral (KV) vaccine given intramuscular (IM).

Materials and Methods: Three groups ($n = 30$ /group) of Angus-cross suckling beef calves, between 3 to 6 weeks of age, were vaccinated either with a commercial MLV, BHV-1/PI3 vaccine IM, or IN, or with a KV BHV-1/PI3 vaccine IM. Control calves ($n = 20$) were injected IN with vaccine diluent. Serum samples were collected from all calves at the time of vaccination to assay BHV-1 and PI-3 maternal antibody titres. Serum samples were collected again when calves were 5 months old to assay antibody titres and 20 calves/group were selected that were seronegative for both BHV-1 and PI3. Calves were weaned at 6 months of age and the selected seronegative calves received either no vaccination ($n = 10$ /group) or a secondary vaccination matching the primary vaccination ($n = 10$ /group). Four days after vaccination all calves were aerosol challenged with 5×10^7 plaque forming units (pfu) of a clinical BHV-1 isolate (isolate 108). Calves were monitored daily for 10 days for clinical signs of disease (fever, weight loss), virus shedding in nasal secretions, interferon-gamma (IFN-g) secretion in nasal secretions, and BHV-1-specific antibody responses.

Results: The assay of serum VN antibody titres confirmed that all calves had high levels of maternal antibody when vaccinated at 3-6 weeks old but antibody was no longer detectable at 5 months of age. Following BHV-1 challenge, the naïve Control group shed detectable levels of

BHV-1 on all days post-infection (pi) and virus shedding exceeded 10⁶ pfu/ml of nasal secretion on day 5 pi. These calves also displayed a significant ($P < 0.05$) increase in body temperature between day 2 to 5 pi and a significant decrease in body weight between day 2 to 10 pi. Elevated IFN-g levels (>9000 ng/ml) were detected in nasal secretions on days 3 and 6 pi. In contrast, calves receiving an IN vaccination at 3-6 weeks and 6 months of age displayed no significant increase in body temperature, did not lose weight, and shed less than 10² pfu of BHV-1/ml of nasal secretion. Calves receiving one or two IM injections of the KV vaccine displayed similar fever, weight loss, and virus shedding as naïve controls. Calves receiving one or two IM injections of the MLV vaccine had a significant decrease in fever and weight loss but shed a similar level of virus in nasal secretions when compared to the naïve controls. Relative to the naïve controls, all vaccinated calves displayed significantly lower IFN-g levels in nasal secretions and significantly increased BHV-1-specific serum antibody responses on day 10 pi.

Conclusions: Our study shows only the IN vaccination of young calves IFOMA induced sufficient immune memory to support rapid induction of a protective secondary immune response 4 days prior to BHV-1 challenge. Changes in the IFN-g and serum antibody responses support the conclusion IM injection of KV and MLV vaccines IFOMA can induce immune memory. However, this immune memory was insufficient at 5-6 months of age to support the rapid induction of a protective immune response. In conclusion, IN but not IM vaccination, with a MLV BHV-1/PI-3 vaccine IFOMA can be combined with a secondary IN vaccination at weaning to induce protective immunity < 4 days.

IM-032-001

Evaluation of a computer-aided lung auscultation system for diagnosis of bovine respiratory disease in feedlot cattle

Edouard Timsit^{1,2,*}, Calvin W. Booker², Afra Verena Mang³, Sebastien Buczinski⁴

¹Production Animal Health, University of Calgary, Faculty of Veterinary Medicine, Calgary, ²Feedlot Health Management Services, Okotoks, ³University of Calgary, Faculty of Veterinary Medicine, Calgary, ⁴Faculté de Médecine Vétérinaire, Université de Montréal, St-Hyacinthe, Canada

Objectives: A computer-aided lung auscultation system (CALA; Whisper stethoscope, Geissler Corporation, Minneapolis, USA) was recently developed to diagnose bovine respiratory disease (BRD) in feedlot cattle.

The objectives were (i) to determine, in a case-control study, the level of agreement between CALA and veterinary lung auscultation and (ii) to evaluate the sensitivity (Se) and specificity (Sp) of CALA to diagnose BRD in feedlot cattle.

Materials and Methods: 561 Angus-cross steers (initial body-weight = 246 ± 45 kg) were observed during the first 50 days after arrival at a feedlot. Steers with visual BRD signs (identified by pen checkers) were examined by a veterinarian, including lung auscultation using a conventional stethoscope and CALA that produced a lung score from 1 (normal) to 5 (chronic). For each steer examined for BRD, 1 apparently healthy steer was selected as control and similarly examined. Agreement between CALA and veterinary auscultation was assessed by kappa statistic. CALA's Se and Sp were estimated using Bayesian latent class analysis.

Results: Of the 561 steers, 35 (6.2%) were detected with visual BRD signs and 35 were selected as pen-matched controls. All steers with visual BRD signs had abnormal lung sounds (i.e. increased bronchial sounds and/or crackles and/or wheezes) detected by veterinary auscultation. Interestingly, 9 steers selected as controls had also abnormal lung sounds. A CALA score was obtained from all examined steers (n = 70), with scores ranging from 1 to 5. Comparison of CALA results with veterinary auscultation (using a CALA score ≥ 2 as a cut-off) revealed a substantial agreement (kappa = 0.77; 95% CI, 0.62-0.92), with 62 concordant results out of the 70 clinical examinations. The 8 discordant results were attributed to the presence of abnormal lung sounds (i.e. increased bronchial sounds and/or crackles and/or wheezes) detected by veterinary auscultation, but not by CALA. Using latent class analysis, CALA had a relatively high Se (92.9%; 95% credible interval [CI] = 0.71-0.99) and Sp (89.6%; 95% CI = 0.64-0.99) for diagnosing BRD compared to pen checking.

Conclusions: CALA had good diagnostic accuracy (albeit with a relatively wide CI). Based on the relatively high specificity for CALA, we inferred that this technology has the potential to significantly decrease the proportion of cattle falsely diagnosed with BRD and thus, could promote prudent use of antimicrobials in commercial feedlots (by reducing unnecessary treatments).

Gilles Fecteau^{1,*}, André Desrochers¹, David Francoz¹, Marie Babkine¹, Sylvain Nichols¹

¹Sciences Cliniques, Faculté de Médecine Vétérinaire, Université de Montréal, Saint-Hyacinthe, Canada

Objectives: The objective of this study was to identify simple potential prognostic indicators amongst the down cow population presented to the Large Animal Clinic at the Faculté de Médecine Vétérinaire at Université de Montréal (CHUV).

Materials and Methods: A retrospective study of recumbent cows (RC) admitted to the Large Animal Clinic at the Faculté de Médecine Vétérinaire at Université de Montréal (CHUV) was conducted. The medical files were reviewed and the following variables were extracted: number of cases per year, survival, days of recumbency prior to presentation, number of days of hospitalization, number of days of flotation therapy (FT), clinical diagnose(s), serum biochemistry profile parameters (Aspartate Aminotransferase (AST), Creatine Kinase (CK), Calcium (Ca), Potassium (K), Phosphorus (P), Carbon Dioxide (CO₂) and Betahydroxybutyrate (BHB)). Mean, median and 95% confidence intervals (CI) were calculated for continuous variables. Mean values for survival (SC) and non-survival cows (NSC) were compared with Z test. Biochemistry parameters were categorized according to their reference values into low, normal and high. Chi-2 test was used to evaluate the relationship between these categorized parameters and the survival. All differences were considered significant if P<0.05

Results: A total of 1116 RC were admitted to the CHUV between March, 1995 and June, 2014. The number of days of recumbency varied from 1 to 22 days (mean=4.5, 95%CI: 4.2-4.7). The mean number of days of recumbency at the farm was not different between SC (4.5 days; 95%CI: 4.2-4.8) and NSC (mean: 4.4 days; 94%CI: 4.1-4.8).

Among all the cases, 565 cows (50.6%) survived. The number of days of hospitalization varied from 1 to 55 days (mean=7.7 days; 95%CI: 7.3-8.1). A total of 976 cows (87.5%) received FT. Duration of FT varied from 1 to 22 days (mean=3.2 days; 95%CI: 3.1-3.4). Mean number of days of FT was not different between SC (mean: 3.3 days; 95%CI: 3.1-3.5) and NSC (mean: 3.1 days; 95%CI: 2.9-3.4).

A serum biochemistry profile was performed on 1028 cows (92.1%). The mean AST for NSC (n=465) was 855 IU/L (95%CI: 784-925) and for SC (n=523), it was 489 IU/L (95%CI: 447-531). The mean CK for NSC (n=459) was 24 175 IU/L (95%CI: 20923-27427) and for SC (n=518), it was 11705 (95%CI: 9919-13491). In general, values of BHB were significantly higher among NSC than SC, while CO₂ was significant higher among SC than NSC. Values of Ca and K were not statistically different between SC and NSC.

The relationship between the biochemistry results by category and cow's survival was not statistically significant for Ca, P, and K (P>0.05). However, a statistically significant association between categorized results and cow's survival was observed for CO₂ (Chi-2=8.8; P=0.012) and BHB (Chi-2=6.3; P=0.043). When CO₂ result was normal or high the proportion of survival cows was higher (53% and 57%).

Conclusions: Establishing a prognosis remains a challenge. Some basic clinical parameters are associated with a reduce chance of survival however each case remains unique and a methodical, rigorous, and systematic approach is the only way to increase the chances of success. Down cow syndrome remains a frustrating problem for the veterinarian practitioner. New ways to assist in lifting the cows could lead to better evaluation, more accurate diagnosis, and ultimately improved accuracy of prognosis

IM-032-002

Retrospective study of cases treated with flotation therapy at the Large Animal Clinic at the Faculté de Médecine Vétérinaire, Université de Montréal

IM-032-003

Anaplasmosis, an underdiagnosed disease in Irish Cattle HerdsJohn Gilmore^{1,2,*}, Mikhail Nosov¹¹FarmLab Diagnostics, ²Emlagh Lodge Veterinary Centre, Co. Roscommon, Ireland

Objectives: Review of the clinical presentation of anaplasmosis from a herd which the author was involved in investigating and treating. Additionally diagnostic test results are reviewed for anaplasmosis tests at FarmLab Diagnostics.

Materials and Methods: Testing was carried out on samples which were submitted for diagnostic testing at FarmLab Diagnostics. Samples originated from a variety of Irish veterinary practices including the practice where the author is a partner. Submitting Veterinary Practitioners requested that samples be tested for Anaplasmosis using RT-PCR. Multiple samples from the same farm were pooled before DNA was extracted. DNA was extracted from EDTA blood samples by EZNA Blood DNA extraction kit (VWR, Ireland). The multiplex TaqMan PCR was performed with specific primer sets on Mx3005P Thermocycler (Agilent Technology).

Results: Laboratory investigation of a dairy herd showed that anaplasmosis was responsible for a clinical syndrome involving pyrexia and milk drop over a prolonged period. Approximately 25% of laboratory submitted samples in suspect cases, tested positive for anaplasmosis. Samples were tested using specific PCR primers to determine the species of *Anaplasma* involved. Approximately half, tested positive using *Anaplasma marginale* specific primers, while the remainder tested positive using *Anaplasma phagocytophilum* primers

Conclusions: The clinical importance of Anaplasmosis in Irish cattle herds is likely to be underestimated, it should be considered as a differential diagnosis of milk drop syndrome. RT-PCR testing of individual or pooled blood samples provides a highly sensitive and specific means of diagnosis. Further investigation on the significance of this disease may be warranted.

IM-032-004

Inter-rater agreement and diagnostic accuracy of lung auscultation to detect calf pneumoniaBart Pardon^{1,*}, Bonnie Valgaeren¹, Piet Deprez¹¹Large Animal Internal Medicine, Ghent University, Merelbeke, Belgium

Objectives: A more rational use of antimicrobials for bovine respiratory disease (BRD) would imply only antimicrobial treatment of animals with a bacterial pneumonia and not systematically in upper respiratory tract infections. Lung auscultation is traditionally used to diagnose pneumonia in a calf with respiratory signs. Information on agreement of lung auscultation between different veterinarians is not available. Also its diagnostic accuracy compared to thoracic ultrasonography, the most sensitive and specific technique to detect pneumonia available in practice, is not determined.

Materials and Methods: The study was conducted in three Dutch veal farms in three different sessions on consecutive days. A calf pen which was recently diagnosed by the farmer as suffering from BRD was selected beforehand. Participants were asked to auscultate the

lungs of all calves present in this pen (8-10), as they daily perform in practice. They reported their findings as a binary variable (normal vs. pneumonic) to a recorder located outside the pens. Veterinarians were only allowed to auscultate and specifically asked not to perform other clinical examinations. Afterwards all calves were examined by thoracic ultrasonography with a 7.5 MHz linear probe (Mylab One, Esaote) by a single operator. Pneumonia was defined as a consolidation of >1 cm². Kappa statistics, Cohen's and Fleiss's, were calculated to estimate agreement of auscultation with ultrasonography and inter-rater agreement, respectively. Diagnostic accuracy of lung auscultation was determined by calculation of sensitivity (Se) and specificity (Sp) with ultrasound as gold standard.

Results: A total of 49 Dutch vets participated in three different sessions. The % of calves with consolidations was 63.0%, 78.0% and 60.0% in sessions 1 to 3, respectively. The mean kappa value for the agreement of auscultation with ultrasonography was 0.38 ± standard deviation (SD)= 0.22 (Range (R)= 0.10-1.0), which is only 'fair' according to Cohen's classification. This agreement was not influenced by session, gender or years after graduation of the participants. Average Se and Sp of lung auscultation were 0.63 (SD= 0.2; R= 0.2-1.0) and 0.46 (SD= 0.3; R= 0.0-1.0), respectively. Of the participants, 8.2% was 100% sensitive, 16.3% was 100% specific, and only 4.0% was perfect. Inter-rater agreement, expressed by Fleiss Kappa, was 0.17 (95% confidence interval (CI)= 0.13-0.22), 0.24 (95% CI= 0.19-0.29) and 0.06 (95% CI (-0.03-0.16)) for sessions 1 to 3, respectively. These values signify a poor inter-rater agreement.

Conclusions: In conclusion, the average low Se and Sp of lung auscultation and only fair agreement with ultrasonography do not support its use as a definite criterion to confirm pneumonia and initiate antimicrobial treatment in a veal setting. Despite that some veterinarians were highly accurate, the variation between veterinarians was extremely large. Better training in lung auscultation or alternatively the use of more standardized techniques such as ultrasonography or electronic stethoscopes is recommended.

IM-032-005

Acute Bacterial Pleuropneumonia in adult dairy cows: A retrospective study of post mortem casesColin Mason^{1,*}¹SAC Veterinary Services, Dumfries, United Kingdom

Objectives: Feedback from practitioners suggests that respiratory disease in adult dairy cows is becoming a more common clinical presentation in practice. In some situations the clinical signs can be severe and acute, with a poor treatment response.

The disease syndrome has a varied potential aetiology including infectious agents and a range of potential animal, management and environmental risk factors.

The aim of this study was to review cases of acute bacterial pleuropneumonia (ABP) examined at post mortem to gain a better understanding of the aetiology and management of this condition.

Materials and Methods: 26 cases of ABP in adult dairy cows based on a gross pathological case definition were examined post mortem at Scottish Disease Surveillance Centres between 2005 and 2015. A standard case definition was used and cases where other diagnoses of respiratory disease were made were excluded from the study.

At post mortem a standard tissue set was collected from each case to allow bacterial and mycoplasma cultures, respiratory virus detection by PCR and histopathology.

Herd and clinical case histories were collected using a standard pro-forma and clinical information was provided by the referring veterinary surgeon.

This descriptive data was reviewed and is summarised in this presentation.

Results: Cases were received from larger, open, expanding dairy herds with some or all cattle housed. It is acknowledged however that these farms are typical of those seen in the area.

There was no seasonal or age trend in affected cattle and 50% of cases occurred within 2 months of calving. All cows were treated with antibiotics prior to either dying or being euthanased on welfare grounds.

The clinical signs were acute, with severe or complete milk drop, anorexia, pyrexia, tachypnoea and severe dyspnoea.

The pathology seen in all cases was an acute fibrinous, bronchopneumonia with pleurisy. Histopathology confirmed an acute suppurative pneumonia consistent with a bacterial aetiology. *Mannheimia haemolytica* and *Pasteurella multocida* were the most common bacterial isolates. No evidence of viral involvement was detected in these cases either by virus detection methods or histopathology.

Potential risk factors were identified on each farm, although these were not tested by a case control study approach. Risk factors included poor housing ventilation, overstocking, poor ventilation of collecting yards, biosecurity, poor transition cow management, heat stress and a previous episode of calf pneumonia.

Conclusions: It was concluded that ABP is a significant disease problem in affected herds and a welfare problem for affected cattle. It is of note that the pathology seen was consistent with a primary bacterial aetiology and no evidence of viral involvement was detected. This information along with potential risk factors identified could allow the practitioner to focus on critical areas for control and prevention of this disease syndrome.

Comments: This work was funded by the Scottish Government's Veterinary and Advisory programme.

LA-035-001

The Effect Of Lameness Before And During The Breeding Season On Fertility In 10 Pasture-Based Irish Dairy Herds

Joris R. Somers ^{1,*}, Jon N. Huxley ², Ingrid I. Lorenz ¹, Michael L. Doherty ¹, Luke O'Grady ¹

¹School of Veterinary Medicine, University College Dublin, Dublin, Ireland, ²School of Veterinary Medicine and Science, The University of Nottingham, Leicestershire, United Kingdom

Objectives: The effects of lameness on fertility have been documented frequently but few data are available from seasonally breeding, pasture-based herds (such as those used in Ireland) where cows are housed during the winter months but managed at pasture for the remainder of the year. This study determined the prevalence of lameness in a group of 786 cows in 10 pasture-based Irish dairy herds before, during and after the breeding season and assessed the relationship between lameness and the reproductive performance in these herds through serial locomotion scoring during the grazing period.

Materials and Methods: This prospective observational study was carried out in 2013 on 10 commercial Irish dairy farms, as part of the on-going herd health management programme conducted by University College Dublin (UCD). All the farms used seasonal breeding and were visited by a UCD veterinarian every 21 days during the calving and breeding season. Reproductive performance was monitored at a herd-level based on Submission rate, Conception risk and Pregnancy rate. Lameness data were gathered by means of serial locomotion scoring of all the animals in the spring breeding herd. Four locomotion scoring visits were scheduled in accordance with the breeding season to allow for cows to be locomotion scored before, during and after the breeding season. Kaplan-Meier survival curves were used to compare the PR distribution and to calculate median days to conception. A Cox proportional hazards model with lameness as time varying covariate was used to identify variables influencing the PR.

Results: Lameness prevalences of 11.6% before, 14.6% during and 11.6% after the breeding season were found. The median days to conception was 26 for cows never observed lame, 33 for cows lame before the start of breeding but no longer lame during the breeding season, 36 for cows that became lame during the breeding season and 43 for cows lame both before and during the breeding season. After controlling for the effect of, farm, month of calving, body condition score at calving, body condition score loss after calving and economic breeding index in the Cox proportional hazards model, cows identified as lame during the study were less likely to become pregnant. Cows lame before the earliest serve date but no longer lame during the breeding season, cows becoming lame after the earliest serve date and cows identified lame both before and after this date were respectively 12%, 35% and 38% less likely to become pregnant compared to cows never observed lame during the study. However, these findings were only significant for cows becoming lame after the earliest serve date and cows lame both before and after the start of breeding.

Conclusions: The lameness prevalence found in this study compared favourably to results from housed cattle and is similar to other studies carried out in grazing herds. The reproductive efficiency was significantly ($p < 0.05$) lower in cows becoming lame during the breeding season and cows lame before and during the breeding season compared to non-lame cows. The PR was not significantly ($p > 0.05$) lower in cows no longer lame during the breeding season compared to cows never diagnosed as lame. In addition to lameness status, nutritional status and genetics were found to influence the reproductive performance in pasture-based Irish dairy herds.

LA-035-002

Applying A Scientific Based, Standardized Footbath Protocol: The Impact On Digital Dermatitis Dynamics

Karin Orsel ^{1,*}, Laura Solano ², Charlotte Pickel ¹, Dorte Dopfer ³, Herman Barkema ¹

¹Production Animal Health, university of calgary/veterinary medicine, ²Production Animal Health, University of Calgary, Calgary, Canada, ³School of Veterinary Medicine, Madison, United States

Objectives: Digital dermatitis (DD) is the most prevalent foot lesion in Canada. The most common on-farm prevention strategy is the use of footbaths. However, there is a wide variability in on-farm practices related to footbath management; including dimensions, frequency of use, products used and concentration. Despite a wealth of information regarding effective practices in the scientific literature, there seems to be a knowledge translation gap between research and on-farm application. Therefore, the objective of this study was to evaluate the effectiveness of a science-based standardized footbath protocol in the field as a preventive measure for DD.

Materials and Methods: A longitudinal field trial was conducted on 9 Alberta dairy farms over 7 months. Each farm served as its own historical control, where 1,300 cows were evaluated before and after the introduction of a new footbath and protocol. The intervention consisted of implementing a computerized automated footbath on all farms using a standardized protocol based on literature recommendations of footbath design (300 cm long x 50 cm wide x 15 cm high), product (CuSO₄), concentration (5%), and frequency (4 milkings). A computerized program dictated the automated mixing of CuSO₄ at a 5% concentration during 4 consecutive milkings on a weekly basis and refreshed the footbath solution every 200 cow passes or less.

DD scoring was done in the milking parlour (every 2 weeks) and confirmed with the gold standard of hoof trimming observations (at the beginning, half-way and end of the study) using the M-stage scoring system and interpret as lesion, active lesion and chronic lesion. In cases with more than one lesion per foot or cow, the most severe lesion was considered for analysis according to the proposed hierarchy of M2 > M4.1 > M4. Initial results were analyzed using paired T-tests. Survival analysis will be applied for a better insight in the preventive effect of the standardized footbath protocol.

Results: Controlling footbath dimensions, along with CuSO₄ concentration and frequency of use, and refreshment of solution, resulted in a change in DD dynamics. A significant decrease in the prevalence of active M2 lesions (from 21 before to 8% after intervention; $P < 0.05$) and an increase of chronic M3-M4 lesions (from 41 before to 55% after intervention; $P < 0.05$) was detected when cows were scored in the milking parlour. A similar trend was identified when cows were evaluated in the trim chute. All farms had a significant increase in the prevalence of absence of lesions (M0), from 31 before to 40% after intervention ($P < 0.05$). The prevalence of cows with active lesions decreased from 41 to 25%, whereas the prevalence of cows with chronic lesions increased from 28 to 35% (before compared to after intervention, $P < 0.05$).

Conclusions: The use of a standardized footbath protocol significantly decreased the presence of active DD lesions and increased the number of cows without lesions as observed in the trim chute. A more precise application of footbath management guidelines as recommended by scientific literature can result in control of DD dynamics to a steady state, with a significant reduction of new cases and well-regulated presence of chronic lesions. In conclusion, controlled and standardized footbath management can result in significant reduction of the prevalence of DD.

LA-035-003

Treating claw horn lesions: Three randomised controlled trials

John Remnant ^{1,*}, Heather Thomas ¹, Oliver Maxwell ², Jon Huxley ¹¹School of Veterinary Medicine and Science, University of Nottingham, Loughborough, ²Scarsdale Veterinary Group, Derby, United Kingdom

Objectives: Lameness is a common condition affecting the welfare and production of cattle globally. Despite this there are few published clinical trials investigating cow level treatments, particularly of the diseases of claw horn disruption (principally sole ulcer, sole haemorrhage and white line disease). The authors have recently conducted three randomised controlled trials, two comparing treatments for lame cows with claw horn lesions and one evaluating the preventive effect of foot trimming in primiparous heifers.

Materials and Methods: The first trial was a randomised, positively controlled clinical trial comparing four treatments for newly lame cows with claw horn disease in 183 dairy cows from five farms in the UK. Cows were locomotion scored fortnightly and were eligible for recruitment if they presented with a new case of lameness in a single hindlimb. Enrolled cows were randomly allocated to receive 1. A therapeutic foot trim only, 2. A trim and foot block, 3. A trim and non-steroidal anti-inflammatory drug or 4. A trim, foot block and NSAID.

The second trial was also a randomised, positively controlled clinical trial comparing three treatments for claw horn disease in 156 cows from seven UK dairy farms. Cows were randomly allocated to receive a trim only, a trim and foot block or a trim block and NSAID. In contrast to the first trial cows were only eligible for enrolment following multiple presentations as lame at fortnightly locomotion scoring, resulting in selection of more chronically lame cows which had been locomotion score lame for at least two weeks.

The third trial was a negatively controlled randomised clinical trial evaluating the impact of an early lactation foot trim on production in 282 primiparous heifers from eight dairy farms in the UK. Heifers between 50 and 80 days in milk were randomly allocated to either untreated control groups or to a treatment group. Heifers in the treatment groups received a functional foot trim and if required a therapeutic foot trim.

Results: In the first trial, based on having a sound locomotion score 35 days after treatment the cure rates were 24.4%, 35.9%, 28.6% and 56.1% for the trim-only, trim and block, trim and NSAID, and trim block and NSAID group respectively. Compared with group 1, cows in group 4 were significantly more likely to be sound at outcome (Thomas et al, *Journal of Dairy Science*, 98(7) p.4477).

In the second trial no differences were detected between treatments and the percentage of cows locomotion scored as non-lame after 6 weeks was around 15% for all groups. This is markedly lower than the newly lame cows in the first trial. Importantly a large number of animals had become lame on the opposite hind leg i.e. the treated leg had improved but they remained lame (Thomas et al, *Veterinary Record*, In Press).

In the third trial no significant difference in 305 day milk production or 100 day in calf rates was detected between groups. Multivariable modelling identified a large increase in milk yield for heifers identified as lame at the time of enrolment in the treatment group compared to non-lame heifers in the control group. On examination, 95% of animals in the treatment group had some pathology identified on at least one claw (Maxwell et al, *Veterinary Record*, 177(4) p. 100).

Conclusions: The authors conclude that screening for, and treatment of, newly lame cows should be carried out fortnightly and cows treated for claw horn disease should receive treatment with a foot block and NSAID wherever possible. The difference in cure rate between the first

and second trial is striking, the key difference being that cows in the second trial were not treated immediately they became lame. The third study also highlights the large number of heifers with pathology at an early stage, and clearly shows a production benefit to treating those identified as lame early in lactation.

Comments: The authors would like to thank the following people who all contributed to the studies described: S. Archer, N. Bell, N. Bollard, A Burrows, C Hudson, C Mason, G Miguel-Pacheco, P Sleeman, H Whay. The work described was funded by The Animal Welfare Foundation (<http://www.bva-awf.org.uk/>) and The Agriculture and Horticulture Development Board (AHDB) Dairy Division, a levy board, not for profit organisation working on behalf of British Dairy Farmers, the authors gratefully acknowledges their support.

Developing A Lameness Detection Model Using Automatically Recorded Performance And Behavior Data

Katharina Schindhelm ^{1,*}, Bernhard Haidn ¹, Andrea Fiedler ², Sven Reese ³¹Bavarian State Research Center for Agriculture, ²Praxisgemeinschaft fuer Klauengesundheit, ³Ludwig-Maximilians-Universität, Munich, Germany

Objectives: Lameness impairs welfare and performance in cows (Green, 2009, Von Keyserlingk, 2009). The increasing size of modern dairy herds leads to lower surveillance rates per individual. Additionally producers often do not recognize lame cows until they suffer from severe stages of lameness. These problems can be the reason for delayed diagnosis and as a consequence thereof substantial deprivation of the well-being of the affected animals.

In the study automatically recorded behavior and performance data were analyzed in order to detect lameness in dairy cows.

Materials and Methods: 65 Simmental cattle housed in a free stall barn were observed from April 2014 to April 2015. In order to measure individual performance (milk yield, live weight, feed intake) and behavior (feeding behavior, standing, lying and activity index) various sensors were installed. A locomotion scoring according to Sprecher et al. 1997 (1-5, 1 = healthy, 5 = severely lame) was made weekly for the entire herd to determine lame and non-lame animals. Receiver Operating Characteristic (ROC) analysis was used to find out about the parameters with the highest accuracy to predict lameness. These will be fitted in a lameness detection model.

Results: Performance parameters such as milk yield, live weight or feed intake did not show a significant change in early stages of lameness. Behavior associated parameters like feeding duration, feeding rate, duration of lying bout or total lying time were more sensitive in terms of lameness prediction. Hence these were included in the lameness detection model. Also days in milk and number of lactation were included as influencing factors.

The preliminary model applied to the recorded data classified 113 of 114 non-lame individuals and 8 of 11 lame cows correctly.

Conclusions: Lameness detection through analysis of feeding and lying behaviour can be a powerful tool to detect lameness automatically in modern free stall barns. Further research is needed to validate the findings of this project in a more significant number of individuals, different breeds and with a more practical, application-oriented environment.

LA-035-005

To bandage or not bandage: The curative effect of bandaging digital dermatitis lesions

Marcus Klawitter ¹, *Dörte Döpfer ², Theo Braden ³, Kerstin E. Müller ⁴

¹Clinic for Ruminants and Swine, Free University of Berlin, Berlin, Germany, ²Department of Medical Sciences, School of Veterinary Medicine, UW-Madison, ³MSSW, School of Medicine, UW-Madison, Madison, WI 53706, United States, ⁴Clinic for Ruminants and Swine, Free University of Berlin, Berlin, Germany

Objectives: Digital dermatitis (DD) is an infectious claw disease that causes lameness among cows worldwide. Efforts to eradicate DD have been overly focused on treatment and less so on standardized maintenance practices, like bandaging, to enhance the effects of treatment. Very few studies have compared the effectiveness of bandaging to non-bandaging. In an attempt to examine the fit of bandaging in the treatment of DD, this study will examine the effect of bandaging on wound size and locomotion among a sample of dairy cows receiving either antibiotic or non-antibiotic treatment.

Materials and Methods: Animals

This randomized clinical trial study included (N=162) Holstein Friesian dairy cows, diagnosed with ulcerative DD lesions (M2) upon the first examination (week 0). Cows, ranging from heifers to cows in their 4th lactation, were housed in a stable fitted with cubicles and with concrete flooring.

Treatment and Evaluation

All hoofs were cleaned and trimmed by a professional hoof trimmer or a veterinarian. The M2 lesions of cows in the first arm of the study (N=85) were sprayed with CTC, a topical treatment containing chlortetracycline (WdT, Garbsen, Germany). Cows were then randomly assigned into either a non-bandaged (N=41, 48%, Group 1) or bandaged group (N=44, 52%, Group 2). A topical non-antibiotic gel, containing activated copper and zinc chelate (Intra Hoof-fit gel [IHF], intra Care b.v), was applied to the M2 lesions of cows in the second arm of the study (N=78). Cows were then randomly assigned into either a non-bandaged (N=40, 51%, Group 3) or bandaged group (N=38, 49%, Group 4). The bandaging process was standardized and applied by the same veterinarian for all groups.

The process of wound healing was evaluated and scored once weekly (weeks 0, 1, 2, 3, 4) according to a visual inspection scheme described by Döpfer et al., 1997 and Berry et al., 2012. Photographs of lesions were taken and later, under the use of a special software package (Jalomed®), were used to track lesion size across observations. The healthy formed skin (M0) was judged as full recovery. Locomotion was also evaluated and scored once weekly according to Sprecher et al., (1997) locomotion scheme.

Results: For cows treated with CTC, (82%, n=38, Group 2) of bandaged and (44%, n=18, Group 1) of non-bandaged cows were deemed macroscopically healed at week 4. A Survival Analysis concluded that healing was significantly higher for bandaged than non-bandaged cows following topical antibiotic treatment (Z = 4.653, p<0.001, 95% CI: 2.19 to 6.84). Furthermore, bandaged lesions were significantly less likely to transition into M4 lesions, the chronic digital dermatitis (p<0.001). For cows treated with IHF, (73%, n=27, Group 4) of bandaged and (30%, n=12, Group 3) of non-bandaged cows were deemed macroscopically healed at week 4. A Survival Analysis indicated that healing was significantly higher for bandaged than non-bandaged cows following topical non-antibiotic treatment (Z=3.352, p <0.001, 95% CI: 1.627 to 6.403). Moreover, bandaged lesions were significantly less likely to transition into M4 lesions, the chronic digital dermatitis (p<0.001). A Wilcoxon Rank Sums Test indicated that bandaging had no effect on locomotion for either cows treated with CTC (W = 13601, p < 0.27, CI:

-4.58e-05 to 1.77e-05) or IHF (W = 14369, p< 0.332, CI: -4.02e-05 to 5.77e-05). However, wound size was significantly larger for cows with locomotion scores between 3 and 5 than for cows with lower scores for both CTC (W = 8621, p<0.019, 95% CI: -2.08 to -0.03) and IHF treatment groups (W = 8051, p<0.001, 95% CI: -2.53 to -0.68).

Conclusions: Results suggest that bandaging accelerated the healing of DD lesions, regardless of treatment type. Bandaged lesions were significantly less likely to develop into stage M4, the chronic stage of digital dermatitis. Thus, our study indicates that covering DD lesions is advantageous to both the wound healing process and the cow's wellbeing.

A randomised clinical trial on the effect of antibiotic or non-antibiotic topical treatment of digital dermatitis in dairy cattle

Ruurd Jorritsma ¹, *Amarins Dotinga ¹, Gerwen Lammers ², Mirjam Nielen ¹

¹Farm Animal Health, Utrecht University, Utrecht, ²Intracare, Veghel, Netherlands

Objectives: Digital dermatitis (DD) is a superficial, painful, contagious epidermitis of the feet of dairy cattle which frequently results in lameness. A common individual treatment for DD in Europe is a topical administration of antibiotic chlortetracycline (CTC) spray. Given potential induction of antibiotic resistance there is a need for effective treatments without antibiotics. We performed a randomised controlled trial to compare clinical improvement of ulcerative DD lesions following treatment with IR spray versus CTC spray (non-inferiority testing).

Materials and Methods: We included 9 dairy herds of around 100 cows housed in a freestall system with an estimated DD prevalence of 20-25%. In total, hind legs of 944 cows from 9 dairy herds were trimmed by professional hoof trimmers and scored using the M1-M4 scoring system. All legs with M2 lesions were included and randomly treated with IR spray or CTC spray according to the instructions of the manufacturers. Clinical improvement was defined as the transition of an ulcerative M2 lesion to any other lesion at treatment evaluation on day 10. At the end of the study 231 cows, of which we included one M2 affected leg each, were eligible for analysis.

Results: After treatment with IR spray, most lesions (71%) transitioned into an M3, while the percentage of M1 and M2 lesions was almost equal (respectively 14% and 13%). After treatment with CTC spray most lesions remained M2 (52%). The percentage of M1 lesions after treatment with CTC spray was a little higher compared to treatment with IR spray (19%). Only 1% and 3% of M2 lesions for respectively IR spray and CTC spray transitioned to M0. The overall clinical improvement rate of IR spray was higher compared to CTC, respectively 86.8% (range 61.5% - 100.0%) and 47.9% (range 17.7 - 85.2%). In all 7 herds clinical improvement was numerically higher for IR spray and in 3 out of 7 herds significantly higher. The Odds Ratio, adjusted for herd effects, for IR spray versus CTC spray was 8.2 (95% CI 4.2 - 15.7) with an estimated Relative Risk of 1.9.

Conclusions: Overall the non-antibiotic IR protocol results in a greater clinical improvement rate than the antibiotic CTC protocol with an Odds Ratio of 8.2 (95% CI 4.2 - 15.7) and an estimated Relative Risk of 1.9. Clinical improvement rates varied between herds, but was numerically higher on all farms for IR spray. The large variation between herds suggests that differences in environmental conditions affect clinical cure.

LA-035-007

Gait cycle in dairy cows and its application to detect lamenessMaher Alsaad^{1,*}, Thomas Hausegger², Ralf Kredel², Adrian Steiner¹¹Clinic for Ruminants, Vetsuisse-Faculty, University of Bern, ²Institute of Sport Science, Faculty of Human Sciences, University of Bern, Bern, Switzerland

Objectives: This study evaluated the feasibility of high frequency accelerometers (400 Hz) to measure gait cycle parameters of stance and swing phases in dairy cows. It was hypothesized that an accelerometer with a high sampling rate (400 Hz) allows for (i) accurate identification and description of the gait cycle pattern in cattle, including the duration and amplitude of swing and stance phases, compared to a high speed camera output, and (ii) a clear distinction between healthy and affected limbs in lame cows.

Materials and Methods: The experimental study was carried out at the Clinic for Ruminants, Vetsuisse-Faculty, University of Bern, Switzerland. Twelve dairy cows without any visible signs of lameness (C) and five lame cows (L) referred to the clinic were used. The measurements of acceleration for groups C and L were conducted during walking in two sessions: Session (I) assessed the accelerations of the metatarsus (MT) and lateral claw of the same limb simultaneously; session (II) assessed the acceleration of the MT of both hind limbs simultaneously to compare the accelerations between left and right MT and calculate the difference for each variable separately (Δ). The extracted gait cycle parameters included (i) several amplitudes (preswing, swing, foot load, ratio of preswing to foot load and the ratio of swing to foot load phase) and (ii) temporal events (relative duration of stance phase and swing phase to gait cycle and of preswing to stance phase).

Results: In session (I), the amplitude of preswing, swing, foot load, ratio of preswing to foot load and ratio of swing to foot load of the lateral claw was significantly higher as compared to the respective MT ($P < 0.05$). The temporal events of the gait cycle, including the relative duration of stance and swing phases of the claw were highly correlated with the MT ($r_s > 0.71$), and only the relative duration of the preswing to stance phase was significantly higher at the level of the MT as compared to the claw ($P < 0.05$).

In session (II), amplitudes and relative temporal events of the gait cycle were not significantly different and moderately to highly correlated ($r_s : 0.52-0.95$) between left and right MT in group C. Δ of the amplitude of foot load, ratio of preswing to foot load and ratio of swing to foot load were significantly higher in group C as compared to group L ($P < 0.05$). All the Δ of the temporal events of the gait cycle were significantly different between group C and group L ($P < 0.05$).

Conclusions: Measuring the gait cycle variables at the level of the MT, using accelerometers with a high sampling rate (400 Hz) is a promising tool to indirectly explore the acceleration of the claw and determine the effect of orthopedic pathologies on the cows' gait.

MC-013-001

A Screening Method To Significantly Reduce The Use Of Intramammary Antibiotics At Drying Off In Dairy Cow Production

Cyril Crosson ^{1,*} and Bioteck Lait Group¹Bioteck Lait, Pacé, Ille-et-Vilaine, France

Objectives: Antibiotics used in agriculture contribute to the development of antimicrobial resistance (Landers et al., 2012) and are the subject of controversy in public opinion. A selective dry cow therapy programme would enable a significant reduction in the use of antibiotics in dairy production. Milk Amyloid A (MAA) has been suggested in several studies as a biomarker of both clinical and subclinical bovine mastitis (Gerardi et al., 2009; Pyörälä et al., 2011). We conducted a field study to evaluate the efficiency of the measurement of MAA when used to make selective antimicrobial treatment decisions at mammary quarter level on cows at drying off.

Materials and Methods: Individual mammary quarter milk samples from 112 cows, originating from low bulk tank somatic cell count (SCC) (<250,000 cells/mL) dairy herds (n=6), were collected between two to seven days prior to drying off (n=445) and after calving (n=339), starting from two weeks until six weeks. All milk samples were cultured for bacterial detection and identification. They were analyzed for SCC and for MAA concentration using a patented commercial ELISA (Tridelta Development Ltd, Maynooth, Ireland). We performed a selective dry cow therapy at quarter level based on MAA results. The quarters from cows with an MAA concentration < 1 µg/mL were not treated with an antibiotic therapy. They were only infused with a teat sealant (n=92). We developed an algorithm to identify an intramammary infection (IMI) at mammary quarter level at the end of lactation based on the gathered MAA and SCC results. The test characteristics of the algorithm were calculated and its negative (NPV) and positive (PPV) predictive values were estimated using the formulas based on Bayes' theorem. Cow/milk data and bacterial culture/detection data were used as a gold standard. Our algorithm was compared with the SCC recording prior to drying off. A threshold of 100,000 cells/mL for primiparous cows or of 150,000 cells/mL for multiparous cows to identify an IMI was used for the SCC test.

Results: The sensitivity and specificity of the developed algorithm were both high, respectively 94.5% and 93.0% and the PPV and NPV in our study population were respectively 96.3% and 89.9%. By contrast, the sensitivity and the NPV of the SCC test were low, respectively 68.7% and 62.8%. As a result, our algorithm could be used to make selective dry cow treatment decisions at quarter level with the confidence that very few infected mammary quarters would be missed and that high proportion of the healthy mammary quarters would be not treated with antibiotic therapy. In contrast, the SCC recording just prior to drying off seems unsuitable as part of this selective programme.

The algorithm's predictive values were both above 90% when estimated in herd populations where the proportion of mammary quarters with an IMI at drying off ranged from 40% to 65%. Similar but more moderated results were obtained for a prevalence ranging from 30% to 75%. Consequently, in these various herds, the proportion of quarters truly infected with a negative test that would not receive an intramammary antibiotic treatment would be low (1 - NPV < 10%) and few quarters truly healthy with a positive test sentence (1 - PPV < 10%) would be treated with an antibiotic therapy.

Moreover, we didn't observe any clinical mastitis six weeks after calving for quarters with a negative algorithmic test that were not treated with antibiotics and were only infused with a teat sealant. These quarters have achieved success in the treatment and prevention of IMI over the dry period.

Conclusions: The use of our screening method for an IMI, based on an algorithm which utilizes MAA and SCC results measured in individual quarter milk samples, in a selective dry cow therapy programme at the quarter level would allow a significant reduction in the use of intramammary antibiotics in dairy production with confidence. In our study, its application would have reduced the use of antibiotic treatments by 29%.

In France since September 2015, we offer a service at drying off for dairy farmers based on our method. The gathered data (MAA, SCC, milk/cow data, bacterial data) are used to grow our database that is used to support our algorithm.

MC-013-002

The attitude of Dutch veterinarians towards antimicrobial use in dairy cows

Christian Scherpenzeel ^{1,*}, T.J.G.M. Lam ^{1,2}¹GD Animal Health, Deventer, ²Dept. Farm Animal Health, Utrecht University, Utrecht, Netherlands

Objectives: Prudent use of antimicrobials in animal husbandry is of major importance in order to reduce the risk of development of antimicrobial resistance. Although on a dairy farm farmers apply most of the antibiotics, the veterinarian as the main advisor on this subject has an important role and responsibility. Understanding the attitude of veterinary practitioners towards antimicrobial use and selective dry cow therapy (SDCT), is crucial in a successful approach of responsible antimicrobial use in dairy practice. The aim of the present study is to describe the attitude of Dutch veterinarians towards antimicrobial use and SDCT on dairy farms.

Materials and Methods: The mindset of veterinarians towards antimicrobial usage in dairy practice and the implementation of SDCT was evaluated retrospectively using a detailed questionnaire. A group of 648 Dutch cattle veterinarians received the questionnaire by e-mail using the software program Survey Monkey. The questionnaire contained items about mindset regarding antimicrobial use, positive and negative aspects of the reduction of antimicrobial use, criteria for selecting cows for SDCT and demographic data. There were open questions, questions with pre-defined answer categories, as well as statements that the farmers rated on a 5-point Likert scale. Results of the questionnaires were summarized and analyzed descriptively to explore the data.

Results: Of the questionnaires sent, 207 (32%) were returned and suitable for analysis. With regard to advice about prudent and restricted use of antimicrobials in general, 71% of the veterinarians see themselves as the main technical advisor, and 56% of the veterinarians are of the opinion that they play a proactive role in the changed policy of restricted use of antimicrobials. A minority of the veterinarians accredit their role negatively; 15% of the veterinarians only see themselves as the messenger of bad news, whereas 9% considers themselves as solvers of a problem the farmer has to handle.

Most of the veterinarians (70%) speak positive about SDCT. The majority of the veterinarians (88%) indicated they judged themselves as being on the right page, with regard to the approach of antimicrobials, and they judge 69% of their farmers is. Almost all veterinarians introduced SDCT to their farmers. Although most of the veterinarians indicated to be concerned about the negative consequences of SDCT, only a minority of them evaluated the implementation of SDCT within one year after introduction.

Conclusions: In general, the mindset of Dutch dairy veterinarians towards the changed approach of antimicrobial usage and the implementation of SDCT was positive. They feel a large responsibility regarding the implementation of the policy of antimicrobial usage and SDCT in the Netherlands.

The practitioners overestimated the problems farmers would have with introducing SDCT on their farms. They can improve their advisory skills by asking the opinion of the dairy farmers, rather than acting based on what their own thoughts are.

MC-013-003

Preliminary Results of an Investigation of the Impact of Bedding Type on Pathogen Load in Bedding, Udder Health and Milk Quality

Andrew Bradley ^{1,2,*}, Katharine Leach ¹, Ian Ohnstad ³, Martin Green ², Victoria Prout ¹, Barbara Payne ¹, David Black ⁴

¹Quality Milk Management Services Ltd, Wells, ²School of Veterinary Medicine and Science, University of Nottingham, Loughborough, ³The Dairy Group, Taunton, ⁴Paragon Veterinary group / XL Vets, Carlisle, United Kingdom

Objectives: There is a general lack of understanding of the impact of different bedding materials, and their management, on milk quality and udder health (Bradley et al., 2014). The aim of this study was to make a quantitative, four-way comparison of the impact of bedding type on pathogen load in bedding, milk quality, udder health and cow comfort using recycled manure solids (RMS) on mats, sawdust on mats, RMS as a deep bed and sand as a deep bed.

Materials and Methods: The study was conducted at Sewborwens Farm, Newton Rigg, Penrith, Cumbria, CA11 0AG, UK. A modified crossover design was employed using four groups of 40 cubicles within a single shed. Each group of cubicles had a different bed type: deep sand (replenished every 2 weeks), deep RMS (replenished twice weekly), RMS on mats (replenished twice weekly) and sawdust on mats (replenished twice daily). Four cow groups, each of 40 cows, were rotated around the four bedding areas, spending two weeks on each bedding type, and cycling twice around the four treatments.

Samples of unused and used bedding were collected every two weeks and a proportional bulk milk sample every week from each of the groups and submitted for microbiological analysis. Individual quarter somatic cell counts were conducted on all cows at the start and end of the study and at each change between bedding materials, allowing intramammary infection (IMI) to be defined by movements around a 100,000 cells/ml threshold. All clinical mastitis cases were sampled and cultured.

Results: There was significant variation in the bacterial load of unused bedding, with counts being significantly and consistently higher in the recycled manure solids than the other bedding materials. In used bedding, counts were typically higher in the deep and shallow RMS beds, and most frequently highest in the shallow RMS beds. The variation in bacterial numbers evident in bedding materials was not evident in milk. With the exception of *Streptococcus* spp and *Staphylococcus* spp counts, no significant differences were detected in the quality of the milk produced by animals bedded on the different bedding materials. Used sand was significantly more likely to contain *Listeria* spp than either sawdust or deep RMS and was significantly more likely to be isolated from milk from cows bedded on sand than on RMS.

The overall proportion of eligible quarters, across all two week blocks of bedding treatments, experiencing an apparent new intramammary infection or an apparent cure were calculated. There was significant variation between the bedding types ($p=0.015$). New IMIs were significantly less likely to occur in cows on sawdust beds than on deep RMS (47/961 vs 84/965; $p=0.012$) or sand beds (47/961 vs 78/965; $p=0.04$). No impact of bedding material on the likelihood of a quarter curing could be identified.

A total of 10 cows developed clinical mastitis during the 16 weeks of the study. *Klebsiella* spp were the most frequently isolated causal organism. There was a trend for cows bedded on RMS to be at higher risk of developing clinical mastitis than cows not bedded on RMS ($p=0.086$).

Conclusions: There were significant differences in the bacterial challenge to teats in different types of bedding and between bed designs when considering RMS. However, with the exception of *Streptococcus* spp and *Listeria* spp there was no clear relationship between bacterial numbers in bedding and in bulk milk, although this may, in part, reflect the hygiene practices during milking and the challenges incumbent in preparing teats on cows arriving from beds constructed with three different bedding materials. In this study, sawdust, applied to mats twice daily, appeared to offer the best protection against new intramammary infection (as measured by SCC).

Effects of antibiotic or non-antibiotic dry off treatment on milk yield, somatic cell count and frequency of clinical and subclinical mastitis

Thomas Wittek ^{1,*}, Claudia Greiner ¹, Alexander Tichy ², Berthold Grassauer ³, Christa Egger-Danner ⁴

¹Vetmeduni Vienna, University Clinic for Ruminants, ²Vetmeduni Vienna, Bioinformatik und Biostatistik, Vienna, ³Tierarztpraxis Grassauer, Ranten, ⁴ZuchtData-EDV-Dienstleistungen GmbH, Vienna, Austria

Objectives: The use of antibiotics in dry cows is widely applied. However, concerns are becoming more evident that antibiotic dry off treatment may result in increasing resistance to antibiotics. The objective of the study was to evaluate the effect of application of long acting antibiotic treatment in comparison to cows which were dried off without antibiotic treatment using large dataset. Primary outcome parameters were milk yield, somatic cell counts and the frequency of clinical and subclinical mastitis. Further thresholds should be calculated for different parameters which should help to decide if antibiotic dry off treatment is indicated or not.

Materials and Methods: As a nationwide health monitoring system for cattle has been implemented in Austria it was possible to use the data on a large number for a retrospective analysis. A large database

was used comprising data on milk yield and health data from the dairy cattle in Austria. The diagnoses of interest for this study were "acute clinical mastitis" and "subclinical chronic mastitis". Further the records were investigated if a long-acting antibiotic dry off treatment had been administered to the cow or not. Further information like animal identification, calving date, milk yield, somatic cell count and information about the herd and the veterinarian were available. The study was conducted on Simmental cows (Fleckvieh) the predominant breed in Austria. The data was filtered and checked for plausibility. Descriptive statistics were calculated (frequency of mastitis, milk yield, somatic cell count) for the previous and subsequent lactations. A model was developed to assess the factors influencing the outcome variables frequency of clinical and subclinical mastitis, A P value < 0.05 was considered indicative for significant differences.

Results: Data of 24,135 dry off treatments and subsequent lactations from 14,301 cows were included. The data was derived from 1,170 dairy farms which contributed between 21 and 129 datasets. Among the 14,301 cows 8,193 (57.3%) were dried off without antibiotic dry off treatment and 6,108 cows (42.7%) were dried off using an antibiotic dry off treatment. The average daily milk yield during 90 DIM was 29.7 ± 6.3 kg/d for 15,516 lactations before Non-AB dry off treatment which was significantly lower than the milk yield of cows in 8,537 lactation which were 31.1 ± 6.7 kg/d which were dried of using an antibiotic treatment. In both treatment groups the average daily milk yield increased from the lactation before dry off treatment to that after. The increments between the previous and the subsequent lactation did not differ between the treatments. The somatic cell count did not differ between the groups before dry of treatment. Equally there were no differences in the subsequent lactation between the different treatments. The incidence of mastitis during lactation and during 90 DIM increased with lactation number for both treatments. The mastitis incidence was higher in the AB group during the lactation before treatment in comparison to the incidence of the non-AB group. However, this difference was still present in the subsequent lactation independently from the dry off treatments.

Conclusions: The results did not support the current belief that milk yield, somatic cell count and the frequency of clinical and subclinical mastitis during subsequent lactation differ significantly between cows which had been dried off using antibiotic treatment and cows which were dried off without antibiotic treatment. The results support the assumption that a blanket antibiotic treatment is no longer justifiable. The present study was not able to suggest cut off values We suggest that other parameters like bacterial culture or on farm culture systems should be investigated. Possibly cut offs have to be determined for each herd individually.

MC-013-005

Systematic review and meta-analysis of the effectiveness of cefquinome treatment protocols of clinical mastitis in dairy cows

Lina M. González ^{1,*}, Hernando G. Gaitán ¹, Claudia G. Cobo ², Javier Sánchez ³, Carlos Lüders ⁴, Alejandro Ceballos ²

¹Universidad Nacional de Colombia, Bogotá, ²Universidad de Caldas, Manizales, Colombia, ³University of Prince Edward Island, Charlottetown, Canada, ⁴Universidad Católica de Temuco, Temuco, Chile

Objectives: To assess the effectiveness of two treatment protocols using cefquinome, a fourth generation cephalosporin, for the treatment of clinical mastitis in dairy cows a systematic review and meta-analysis (MA) of scientific literature was conducted. Our results will allow

evaluating the recommendation on the prudent use of cefquinome in the dairy industry.

Materials and Methods: Randomized clinical trials (RCT) were retrieved using Medline, Science Direct, Web of Science, Cab Abstracts, and Scopus databases. In addition, conference proceedings, the list of references of the included studies, and direct contact with authors were also used as a study search strategy. Studies considering lactating dairy cows diagnosed with any degree of clinical mastitis treated with cefquinome (cefq) were included in the initial search. The following outcomes were selected for the analysis: clinical cure (CC), bacteriological cure (BC), somatic cell count (SCC), milk production, recurrence, and culling. Two reviewers did independent screening of the references, data extraction, and assessed the risk of bias (ROB) of included studies. A random effects MA using the Mantel-Haenszel method was conducted to compare extended therapy (ET) vs standard therapy (ST) in two trials. Results are shown as odds ratios and their confidence interval at 95%.

Results: Four RCT were included. Protocols compared were: (A) Intramammary (IMM) 75 mg every 12 h for 3 times (ST), (B) Protocol A plus intramuscular (IM) injection 625 mg at 0 and 24 h, (C) 75 mg IMM 3 infusions every 12 h plus 3 infusions every 24 h (ET), (D) 75 mg IMM every 12 h on d 1 and once a day for 4 d, and (E) Protocol D plus 1 mg/kg IM every 24 h for 5 times. Overall, ET compared to ST failed to show a benefit on CC, (OR: 1,0 [IC: 0,6-1,7]), BC (OR: 1,3 [IC: 0,9-1,9]), and reduction of quarter-level SCC to <200.000 cel/mL (OR: 1,4 [IC: 0,9-2,1]). After controlling by potential confounders, there was no evidence of improvement in BC (OR: 0,8 [IC: 0,4-1,3]) in a MA of the same two trials. Significant predictors for BC were: staphylococci infections (OR: 0,3 [IC: 0,1-0,9]), the interaction between duration of treatment and streptococci infections (ET over ST) (OR: 3,1 [IC: 1,1-8,9]), and SCC before treatment (OR: 0,4 [IC: 0,2-0,9]). The latter indicates that the higher SCC prior to treatment, the lower cure probability. One study found a significant difference in CC comparing A and C (OR: 3,0 [IC: 1,0-9,2]) by AD, where pretreatment cow udder firmness was a significant predictor of the outcome. Clinical persistence or recurrence was significantly lower when comparing protocols D (OR: 0,4 [IC: 0,1-0,5]) and E (OR: 0,3 [IC: 0,2-0,7]) to protocol A, after survival analysis conducted by the authors where the effect of the farm, quarter location, parity, and use of NSAIDs were significant predictors. Possible risks of selection, detection bias and performance bias were identified.

Conclusions: Results should be cautiously interpreted due to the ROB that might compromise validity. No difference was found in BC, CC or lowering the SCC in the overall MA. No differences in BC were found after controlling for confounders. Clinical cure following ET protocol was different in one study, showing a positive effect. The evidence supports the use of cefq to treat clinical mastitis caused by streptococci following an ET protocol; otherwise, ST should be the choice. Nevertheless, cow factors should be analyzed before treating the case to comply with a prudent use of antibiotics, such as cefq.

MD1-014-001

A randomized clinical trial to evaluate the effectiveness of incomplete milking in early lactation to reduce ketonemia and hyperketonemia

Pierre-Alexandre Morin ^{1,*}, Catarina Krug ², Younes Chorfi ², Jocelyne Dubuc ¹, Jean-Philippe Roy ¹, Pierre Lacasse ³, Débora Santschi ⁴, Simon Dufour ²

¹Département des sciences cliniques, ²Département de pathologie et de microbiologie, Faculté de médecine vétérinaire, Université de Montréal, Saint-Hyacinthe, ³Sherbrooke Research and Development Centre, Agriculture and Agri-Food Canada, Sherbrooke, ⁴Valacta, Ste-Anne-de-Bellevue, Canada

Objectives: Hyperketonemia is a metabolic disorder of dairy cows. Generally, affected animals do not demonstrate clinical signs. It can cause lower milk production, poorer subsequent reproductive performance, predispose to serious illnesses and leads to early herd removal. In order to reduce ketonemia and hyperketonemia during the post-partum period, recent data have shown that limiting fat mobilization in fresh cows could be a relevant strategy. The objective of this study was to quantify the impact of a volume-controlled milking protocol (VCMP) on blood ketonemia and on the occurrence of hyperketonemia during the first 3 weeks of lactation.

Materials and Methods: Thirteen commercial dairy herds located within 100 kilometers of Saint-Hyacinthe (Quebec, Canada) were recruited to participate in a randomized clinical trial. From December 2013 to March 2015, 846 multiparous cows were randomly assigned to the conventional (complete) milking protocol of the farm (CMP) or the VCMP of 10-14 liters per day during the first five days in milk (DIM). A total of 427 and 410 cows were attributed to the CMP and VCMP groups; nine cows were lost to follow-up before start of the milking protocol. Blood β -hydroxybutyrate acid (BHBA) concentration was measured to quantify ketonemia, three times, at weekly interval on each cow between 1 and 25 DIM using a Precision Xtra hand held device (Abbott Diabetes Care, Alameda, USA). Hyperketonemia was defined as BHBA > 1.2 mmol/L. Time period was stratified as: 0-5 DIM (i.e. treatment period), 6-15 DIM (i.e. first 10 days following end of treatment), and 16-25 DIM (i.e. following 10 days). Effect of treatment on ketonemia was investigated using a linear mixed model with the natural logarithm of the BHBA measurement as the dependent variable and with treatment group assignment, time period, and interaction between time period and treatment group as fixed effects. Random effects at cow and herd level were added to adjust for the multiple measurements per cow and the multiple cows per herd. A generalized linear mixed model considering hyperketonemia as dependent variable, using a logit link, and the previously described fixed and random effects, was also developed to investigate effect of treatment on hyperketonemia.

Results: Mean blood BHBA concentrations during the 0-5, 6-15, and 16-25 DIM periods were 0.76 and 0.80, 0.96 and 1.10, and 1.22 and 1.16 mmol/L for the VCMP and CMP groups, respectively. A tendency for lower blood BHBA ($P < 0.08$) in treated cows was observed during the treatment period (i.e. 0-5 DIM), while lower concentrations were observed during the 6-15 DIM period ($P < 0.01$). Mean blood BHBA concentrations were similar between groups during the 16-25 DIM period ($P = 0.37$). The proportion of hyperketonemic cows during the 0-5, 6-15, and 16-25 DIM periods were 8.4 and 12.2, 23.5 and 28.5, and 32.7 and 30.5% for the VCMP and CMP groups respectively. Treatment was not associated with the occurrence of hyperketonemia during the 0-5 ($P = 0.13$), 6-15 ($P = 0.12$), and 16-25 DIM ($P = 0.54$) periods.

Conclusions: The evaluated milking protocol was an effective way to reduce ketonemia during the early postpartum period, but did not affect significantly odds of hyperketonemia. Further studies should

investigate the effect of VCMP on milk production, postpartum diseases, reproduction performance, udder health and culling.

Survey of metabolic indicators in Irish periparturient cows ('transition period')

Denise Murphy ^{1,*}, John Fagan ¹, Seamus Fagan ¹, Donal Toolan ², William Fitzgerald ², Maresa Sheehan ², Micheal Casey ³

¹Department of Agriculture, Food and the Marine, Regional Veterinary Laboratory, Coosan, Athlone, Co Westmeath, ²Department of Agriculture, Food and the Marine, Regional Veterinary Laboratory, Hebron Road, Kilkenny, ³Department of Agriculture, Food and the Marine, Regional Veterinary Laboratories Division, Backweston Laboratory Campus, Co Kildare, Ireland

Objectives: The transition cow period has been defined as the period from 3 weeks pre-calving until 3 weeks post-calving. This is a hugely important period characterised by significant changes in the endocrine status of the cow and the rapid mobilisation of somatic energy & protein reserves due to a reduction in feed intake when nutrient demand for the developing foetus and the upcoming lactation are increasing. The objective of this survey was to use metabolic profiles to monitor the management of cows in the transition period.

Materials and Methods: In the spring of 2015, Athlone and Kilkenny Regional Veterinary Laboratories conducted a transition cow survey within their catchment areas. Over 700 blood samples were received from batches of 6-12 cows in the transition period in 92 different herds. They were tested for the following metabolic parameters: magnesium, inorganic phosphorus, copper, urea, non-esterified fatty acids (NEFA), beta-hydroxybutyrate (BHB) and glutathione peroxidase (GSHPX). Calcium was measured in those cows that were within 48 hours of calving.

Results: Over 70% of these herds had at least one animal with serum magnesium concentrations below reference ranges: these animals are at risk of acute clinical hypomagnesaemia (grass tetany/ grass staggers). Low magnesium may also complicate cases of clinical hypocalcaemia (milk fever). 49% of these herds had at least one animal with serum urea concentrations below reference ranges which may indicate suboptimal protein intake. 50% of the herds with cows within 48 hours of calving ($n = 44$) had at least one of these cows with serum calcium below reference ranges. Two thirds of all herds had at least one animal with serum copper concentrations below reference ranges. Raised non-esterified fatty acid (NEFA) values (> 0.7 mmol/L) were identified in 27% of these herds or 18.6% of the samples tested. This metabolite is an index of negative energy balance and suggests that these animals were not consuming sufficient energy in their diets for the heavy metabolic requirements of late pregnancy & early lactation.

Conclusions: Blood biochemistry profiles are a useful tool in the monitoring and management of the transition cow and in investigating performance-related problems during this critical period. This study suggests that many Irish herds may have indicators of sub-optimal management of transition cows, and that a suite of metabolic indicators should be routinely monitored as an integral part of a comprehensive herd health plan. This survey work will be continued across more regional veterinary laboratories in spring 2016.

ACTH-test sensitivity affects disposition for high body condition in dairy cows during the transition period

Juergen Rehage ^{1,*}, Lena Ruda ¹, Lea Fieguth ¹, Claudia Raschka ¹, Asako Kinoshita ¹, Anja Schacht ¹, Marion Piechotta ¹, Korinna Huber ², Akos Kenez ², Ulrich Meyer ³, Sven Dänicke ³

¹Clinic for Cattle, University of Veterinary Medicine Hannover, Hannover, ²Dep. of Animal Science, Univ. Hohenheim, Stuttgart, ³Dep. of Animal Nutrition, Friedrich-Loeffler-Institute, Braunschweig, Germany

Objectives: In dry dairy cows feeding should be adjusted to requirements to avoid over-conditioning at calving because high body condition is a major risk factor for ketosis in early lactation. However, high body condition appears to have also a genetic and epigenetic background. The individual sensitivity of the hypothalamic-pituitary-adrenal (HPA) axis and the release of cortisol as tested in the ACTH (adrenocorticotrophic hormone) test vary considerably between cows. Thus, aim of the study was to test the relationship between HPA-axis reactivity and body condition in dairy cows during the transition period.

Materials and Methods: In 22 pluriparous German HF Dairy cows, kept in free stalls with cubicles and fed a TMR ration based on grass and corn silage and concentrate, an ACTH challenge was performed on day(d)106 post partum (pp). Before and after injection of ACTH (80µg) cortisol concentrations were measured in blood samples taken in short term intervals from indwelling jugular vein catheters. For statistical evaluation baseline and peak concentrations and the area under the time-concentration curve (AUC) were assessed. By means of sonography subcutaneous (SCAT) and total abdominal adipose tissue mass (AbdomAT) were estimated at d-42, d1, d21 and d100 relative to parturition and their dynamic changes (in kg/d) were calculated separately for the dry and the lactation period. Cows were allocated to three groups, low (N=7), intermediate (N=8), and high (N=7) responder, according to their results in the ACTH test. For statistical evaluation ANOVA for repeated measurements were used with Tukey test for multiple comparisons of means (SAS package 9.3).

Results: Generally SCAT was about half as much as AbdomAT in studied cows ($p < 0.001$). At d-42, d1, d21 and d100 mean SCAT ($p < 0.01$) and AbdomAT ($p < 0.01$) were significantly lower in high compared to intermediate and low responder in the ACTH test. In average high responder in the ACTH test gained in the AbdomAT before parturition and mobilized after parturition from AbdomAT similar amounts as low and intermediate responder. Mean gain and mobilization of fat in SCAT was significantly less before and after parturition in high responder compared to low and intermediate ($p = 0.029$). However, relative to depot sizes of SCAT and AbdomAT mobilization of fat from each depot was not significantly different between groups.

Conclusions: According to results HPA axis sensitivity affect lipid metabolism in dairy cows during the transition period. High responder in the ACTH test are throughout the transition period leaner and mobilize less fat from SCAT after parturition which may affect disposition for subclinical ketosis in early lactation. Lipid metabolism of SCAT and AbdomAT appear to be differently affected by HPA axis sensitivity. The genetic and epigenetic background of HPA axis sensitivity need further evaluation in dairy cows.

MD1-014-004

Subclinical Hypocalcemia In French Dairy Cows: Study In A Veterinary Practice In The Department Of The Ardennes

Marie Gillet ¹, Pierre Kirsch ², Patrick Besnier ³, Yves Millemann ^{1,*}

¹Animal Production and Public Health, Alfort National Veterinary School, MAISONS-ALFORT, ²Clinique vétérinaire des Forges, AUVILLERS, ³Obione, MACON, France

Objectives: As there is not any data on French dairy herds, a study was designed in order to determine if subclinical hypocalcemia also exists in France. For that purpose, calcemia around calving was measured in 106 Holstein cows from a veterinary practice in the Ardennes.

Materials and Methods: The prevalence of subclinical hypocalcemia, i.e. calcemia decrease at calving below 80 mg/L (or 85 mg/L depending on authors) without associated clinical signs, is not described to date in France. Nevertheless, this disease could have a lot of consequences for the dairy cow: it could represent an additional stress at calving, it could also increase early lactation negative energy balance, impair immune system, and make dairy cows more susceptible to postpartum health disorders. According to several American studies, subclinical hypocalcemia could affect up to 25% of primiparous cows and 50% of multiparous cows.

The study was carried out between August and November 2014. Eight different Prim'Holstein herds were included on a voluntary basis. Two herds were organic farms. In total, 106 cows could be recruited during the study period.

Calcemia was measured one week before calving, then 12 to 24 hours, 4 days and 8 days after calving, then each week if calcemia remained below 85 mg/L. Subclinical hypocalcemia threshold retained was 80 mg/L and a cow was considered in subclinical hypocalcemia if one blood sample was below 80 mg/L, without any hypocalcemia clinical sign.

Results: Among the 106 cows included in the study, 45% exhibited subclinical hypocalcemia, notably 16% of primiparous cows and 57% of multiparous cows. A significant association was evidenced between a low calcemia at calving and several postpartum diseases like metritis, mastitis, retained placenta and ketosis ($p = 0.03$ for retained placenta and $p = 0.01$ for at least one of these four diseases). A trend to develop at least one of these diseases was observed for cows with a calcemia under 83 mg/L ($p = 0.06$). A clear association between subclinical hypocalcemia and these diseases was observed from 75 mg/L of calcemia ($p = 0.03$). No significant association was emphasized between on one hand subclinical hypocalcemia and on the other hand body condition score, rumen fill score, lameness score, urinary pH (all those criteria being estimated during the week before calving), magnesemia (at calving), or β -hydroxybutyrate serum concentration (determined at 4 days and 8 days postpartum). However, hypocalcemic cows produced, on average, 4.8 kg more milk in the first month of lactation when compared with other cows ($p < 0.01$). No significant difference about milk quality was found: milk protein content, milk fat content and somatic cell count were not significantly different.

Conclusions: This study is to our knowledge the first that stresses the importance of subclinical hypocalcemia in France and that underlines the association with postpartum diseases in this context. Moreover, subclinical hypocalcemic cows produced on average more milk than control cows.

MD2-015-001

Prepartum plane of energy in dairy cattle: effects on production, energy balance, glucose tolerance, and adipose and muscle tissue insulin signaling

Sabine Mann^{1,*}, Francisco Leal Yepes², Joseph J. Wakshlag³, Thomas R. Overton², Daryl V. Nydam⁴

¹Department of Population Medicine and Diagnostic Sciences, Cornell University College of Veterinary Medicine, ²Department of Animal Science, Cornell University, ³Department of Clinical Science, Cornell University College of Veterinary Medicine, Ithaca, ⁴Department of Population Medicine and Diagnostic Sciences, Cornell University College of Veterinary Medicine, Ithaca, NY, United States

Objectives: The transition from late gestation to early lactation poses tremendous metabolic challenges to dairy cows. Interest lies in providing optimal nutrition during the dry period to improve adaptation to lactation. Overfeeding energy to prepartum dairy cows has been associated with detrimental effects in early lactation. The study objectives were to assess the effect of dry period nutritional strategies varying in energy content on energy balance, milk production, glucose tolerance, and adipose and muscle tissue insulin signaling.

Materials and Methods: Multiparous dairy cows (n=84) were enrolled at dry-off (57 d before expected parturition) in one of three different ad libitum TMR dietary dry period nutritional groups: those fed a controlled energy diet during the entire dry period, formulated to supply 100% of predicted requirements (group C); those overfed energy by 50% of predicted requirements (group H); and those that received the same TMR as group C during the far-off period and then a diet supplying energy in excess of 25% of energy requirements during the close-up period only (group I). Diets were balanced for metabolizable protein and all cows were fed the same fresh cow TMR until the end of the study at 42 DIM. Intravenous glucose tolerance tests (IVGTT) with rapid infusion of 0.25 g/kg of glucose were performed at 28 and 10 days before expected parturition, as well as 4 and 21 days after calving in all cows. Backfat thickness and diameter of M. longissimus dorsi were measured by ultrasonography at six times throughout the study. Subcutaneous adipose and external oblique muscle tissue biopsies were taken at the same time-points immediately before and 60 min after glucose infusion. All IVGTT samples were analyzed for insulin, glucose and NEFA concentrations; baseline samples were analyzed for β -hydroxybutyrate (BHB) and glucagon concentrations. Adipose and muscle tissue protein were extracted from 12 cows each in group C and H, and subjected to immunoblotting, for phosphorylated and total AKT and ERK. Statistical analysis was performed using SAS 9.3 adjusting for multiple comparisons using Tukey's posthoc test.

Results: Compared with cows fed a controlled energy diet prepartum, cows overfed energy during the dry period showed higher concentrations of BHB (0.84 vs. 0.61 mmol/L, $P = 0.04$) and NEFA (0.80 vs. 0.66 mmol/L, $P = 0.02$) postpartum whereas milk production in early lactation was unaffected ($P = 0.98$). Of all cows, 25, 36 and 43 % in groups C, I and H had at least one episode of BHB over the cut-off of 1.2 mmol/L (=positive test). The overall median time to first positive test was 7 days. Within the first 21 DIM, cows in group C, I and H had 13, 32 and 31 test positive episodes out of 250 tests in each group ($P = 0.004$). Dry matter intake (DMI) and energy balance prepartum were higher in cows fed higher energy diets ($P < 0.001$), but DMI did not differ postpartum between treatment groups ($P = 0.99$) although energy balance tended to be less negative postpartum in the controlled energy group ($P = 0.09$). Glucose tolerance and insulin response to a glucose bolus did not differ in the three groups ($P > 0.10$), but baseline concentrations of glucose and insulin 4 days postpartum were lower in cows overfed energy during the whole duration of the dry period ($P \leq 0.09$). Insulin signaling at baseline and in response to an endogenous insulin stimulus measured as the

ratio of phosphorylated to total AKT and ERK did not differ in adipose and muscle tissue biopsies from group C and H.

Conclusions: Overfeeding energy in the prepartum period was associated with increased concentrations of markers of negative energy balance postpartum despite the absence of differences in milk production. Overfeeding in the dry period did not affect insulin sensitivity postpartum in our study. Lower resting glucose concentrations postpartum in the overfed group can be interpreted either as a decreased gluconeogenic capacity or a decreased uptake of glucose in the periphery, however hepatic gluconeogenesis in this study was not determined.

MD2-015-002

A field study about incidence, risk factors, and consequences of ketosis in dairy cattle

Alejandro Bach¹, Cristina Andreu^{3,*}

¹Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, ²Department of Ruminant Production, Institut de Recerca i Tecnologia Agroalimentàries (IRTA), Caldes de Montbui, Barcelona, ³Elanco Animal Health, Alcobendas (Madrid), Spain

Objectives: Dairy cows in early lactation must transition from the demands of late gestation to those of early lactation. Cows failing to adapt commonly incur an elevation of circulating ketone bodies in blood. This condition is known as ketosis.

The objectives of this study were to first determine the incidence of ketosis in different areas and production systems in Spain, and second to identify potential predisposing factors for ketosis and the consequences of this affliction on milk production.

Materials and Methods: Nineteen dairy herds distributed in four distinct areas of Spain (North: 8 herds and 239 cows; Northeast: 5 herds and 1,537 cows; South: 3 herds and 625 cows; and Northwest: 3 herds and 694 cows) were enrolled in this study for a period of 13 months. Average milk production of the 19 herds was 33.4 kg/d. Each herd was visited at least once a week by a veterinarian who collected data about cow performance and disease. All participant veterinarians held a meeting before the initiation of the study to reach a consensus about the criteria for diagnosing retained placenta, metritis, hypocalcemia, and mastitis. Also, each veterinarian collected a blood sample by venipuncture of the coccygeal vessels to determine blood β -OH-butyrate (BHB) concentrations using a cow-side system (Precision Xtra meter, Abbott Laboratories, Abbott Park, IL) between -14 and -7, 1 and 7, and 14 and 21 d relative to calving. At these time points, cows were also evaluated for body condition score (BCS) with scale from 1 to 5. Cows were classified as having subclinical ketosis (SCK) whenever blood BHB was between 1.2 and 3.0 mM, and classified as having clinical ketosis (CK) when blood BHB was ≥ 3.0 mM.

Results: Incidence of ketosis (blood BHB ≥ 1.2 mM) was 28.3%.

Incidence of SCK was greatest in summer and lowest in fall, whereas the incidence of CK was greatest in both spring and summer. Cows that calved in summer had 1.4-fold greater odds ($P < 0.01$) and those that calved in fall had 0.77-fold lesser ($P < 0.01$) odds of having ketosis than those that calved in winter. The odds of having ketosis was 2.25-fold greater ($P < 0.001$) for cows with twins than with cows that had regular calvings. Multiparous cows had 2.34 greater ($P < 0.001$) odds of incurring ketosis than primiparous cows. Furthermore, for every unit (a 'unit' is '0.25') increase in BCS before calving cows had a 2.1-fold increase ($P < 0.001$) in the risk of undergoing ketosis, and for every unit

of BCS loss between 1 week before and 3 weeks after calving, the risk of ketosis increased ($P < 0.001$) 1.96-fold. Multiparous cows producing more milk in the previous lactation were more ($P = 0.04$) likely to develop ketosis than their lower-producing herdmates. Ketosis prevalence was 30.9, 31.1 and 34.2% in cows producing less than 10,800, 10,800-12,700 and 12700-14000 kg in their previous lactation, respectively; and reached 39.7% in cows that produced over 14,000 kg of milk in their previous lactation.

Lastly, cows that incurred ketosis produced more ($P < 0.01$) milk (37.9 ± 1.83 kg/d) during the first 15 weeks of lactation than those that did not (35.4 ± 1.83 kg/d). Cows that had ketosis produced the same amount of milk the first 4 weeks after calving, but they produced more milk than those that did not have ketosis thereafter.

Conclusions: The overall incidence of ketosis was about 28%. Multiparous cows, cows carrying twins, and cows calving in summer have a greater risk of incurring ketosis. And as the difference in BCS between 1 week before and 3 weeks after calving increases the risk of incurring ketosis also increases. Multiparous cows producing more milk in the previous lactation are more likely to develop ketosis in their subsequent lactation than their lower-producing herdmates. Cows that experience ketosis produce the same amount of milk the first 4 weeks of lactation, but then they produce more milk than those that did not have ketosis.

MD2-015-003

Is subclinical hypocalcemia a truly subclinical disorder?

George Valergakis¹, *Evangelos Tsiamadis¹ Georgios Banos¹ Georgios Arsenos¹ Nikolaos Panousis²

¹Laboratory of Animal Husbandry, ²Farm Animal Clinic, Faculty of Veterinary Medicine, School of Health Sciences, Aristotle University of Thessaloniki, Greece, 54124 Thessaloniki, Greece

Objectives: Subclinical hypocalcemia (SCHCa) presents no symptoms related to low serum Ca concentration (< 8.3 mg/dL); cows not recumbent, not showing excitability, nervousness, weight shifting and hind feet shuffling. Given the lack of information regarding clinical examination findings of SCHCa cows, the objective of the study was to investigate any possible association among them.

Materials and Methods: The study was conducted in 8 commercial dairy herds located in Northern Greece, with 770 Holstein cows. Each cow was clinically examined and blood sampled on the 1st and 2nd day after calving. Rectal temperature (RT), heart rate (HR) respiratory rate (RR), number of ruminal contractions per 2 minutes (RC) and rumen fill score (RS) were recorded. Serum Ca concentration was determined with atomic absorption spectrophotometry. Health status was monitored during the first 8 days after calving; cows that presented metritis, mastitis, ketosis or left displaced abomasum were excluded from the study. The final data set included 420 day 1 and 427 day 2 complete cow records, respectively. Clinical examination findings potentially associated with SCHCa were: a) $RT < 38.5$ C, b) $HR > 100$ beats per minute, c) $RR > 50$ breaths per minute, d) $RC < 2$ per 120" and e) $RS < 3$ (5-point scale; 1: empty rumen, 5: well-filled rumen). Their relationship with SCHCa was examined: i) singly, ii) all pair combinations with 1 or both being present, iii) all triple combinations with 2 or 3 being present, iv) all quadruple combinations with ≥ 2 and ≥ 3 being present, and v) all 5 together, with ≥ 2 and ≥ 3 being present. Presence of findings for different SCHCa severity levels was investigated using 3 serum Ca thresholds;

< 8.3 mg/dL (A), < 8.0 mg/dL (B) and < 7.5 mg/dL (C). Sensitivity (Se), specificity (Sp), positive and negative predictive values (PPV and NPV, respectively), and 95% confidence intervals (95% CI) were calculated for all clinical examination findings and SCHCa thresholds combinations.

Results: Prevalence of SCHCa during day 1 was 36.9%, 24.8% and 13.1% for thresholds A, B and C, respectively; that of day 2 was 36.5%, 28.1% and 16.4%, respectively. Se and Sp values were very similar across SCHCa thresholds. Mean Se of all combinations of clinical findings was 0.24 and 0.21, for days 1 and 2 respectively. However, for RS – HR, RS – RR and RS – RT, it ranged from 0.81 to 0.89; Sp was low in these cases: 0.23 and 0.21 for days 1 and 2, respectively. Mean Sp of all combinations of clinical findings was 0.77 for both days 1 and 2. When RC was combined with HR, RR and RT, as pairs or triples with all findings present or when they were all four combined with ≥ 3 findings present, Sp was > 0.90 . Generally, clinical findings combinations had either low Se (< 0.25) - high Sp (> 0.75), high Se (0.80-0.85) - low Sp (< 0.25) or both moderate, ranging from 0.45 to 0.55. Mean PPV differed across SCHCa thresholds and was usually low, 0.39 and 0.36 for threshold A, 0.29 and 0.28 for B, and 0.14 and 0.20 for C, on days 1 and 2, respectively. On day 1, a PPV of 0.67 resulted when RC, RR and RT were combined and all three findings were present (thresholds A and B); 95% CI was 9.4% to 99.2%. On day 2, a PPV of 0.67 resulted when: a) RC and HR were combined and both findings were present (thresholds A, B and C); 95% CI was 22.3% to 95.7%, and b) RC, RR and HR were combined and all three findings were present (thresholds A, B and C); 95% CI was 9.4% to 99.2%. Mean NPV was 0.63 and 0.64 for threshold A, 0.76 and 0.72 for B, and 0.87 and 0.84 for C, on days 1 and 2, respectively.

Conclusions: When present, certain clinical examination findings may be indicative of SCHCa. On day 2, the probability a cow with none or only one rumen contraction per 120" and tachycardia (heart rate > 100) to be subclinically hypocalcemic is 67%. The calculated wide 95% CI range limits the practical application of this finding. More research is warranted towards cowside detection of SCHCa without blood testing.

MD2-015-004

Prevalence of subclinical hypocalcaemia in spring-calving pasture-based dairy herds in New Zealand

Katrina Roberts¹, *Scott McDougall¹

¹ Cognosco, Morrinsville, New Zealand

Objectives: Prevalence of subclinical hypocalcaemia in dairy cows is not well documented in New Zealand. The aim of this study was to estimate the true herd-level prevalence of subclinical hypocalcaemia as measured by serum calcium levels of < 2.0 mmol/L in Waikato dairy herds.

Materials and Methods: Clinically normal mature cows (i.e. ≥ 2 nd lactation; average $n=14.2$ per herd) who were within 48 hours of calving were sampled on one or two calendar days between the 10th July 2015 and 11th August 2015, from 74 spring-calving pasture-based dairy herds from the Waikato region of New Zealand.

Cows were excluded if they had had any antibiotic or anti-inflammatory treatments in the previous 14 days or if they had been diagnosed with any clinical disease around calving.

Cow level data (age, breed, calving date, sampling date and body condition score (on a 1-10 scale) were recorded and a blood sample was collected from the coccygeal vein. Serum samples were analysed for total calcium concentration within 48h of collection by a commercial

veterinary laboratory (New Zealand Veterinary Pathology, Hamilton, New Zealand).

Data were entered into a Microsoft Access database and descriptive statistics performed used StataSE 12.

Results: The average herd size was 467 (range = 160-1100) cows.

The average age of the sampled cows was 5.2 (range 3-13) years, the average BCS was 4.7 (range 3.5-6.5) and the predominant breeds were New Zealand Friesian (44%), Kiwicross (38%) and Jersey (11%).

Cows were sampled on the day of calving (33%), within 24 hours of calving (49%) or within 48 hours of calving (17%).

The average serum calcium concentration for the 1,071 samples was 2.07 mmol/L (SD=0.31 ; Range = 0.99-2.85) and 33% (31-36 95%CI) of animals had concentrations <2mmol/L. The median herd prevalence of subclinical hypocalcaemia was 33% (20-46% IQR).

The prevalence of subclinical hypocalcaemia decreased with increasing time from calving with 46% affected on day 0, 28% on day 1 and 20% on day 2. However, time from calving to sampling was correlated with herd.

Conclusions: This observational study has identified that subclinical hypocalcaemia is highly prevalent in spring-calving pasture-based dairy herds in New Zealand. There is large between-herd variation in the prevalence of this condition. Prevalence of subclinical hypocalcaemia declines with time postpartum. Further work is required to define factors associated with the between-herd variation in this condition.

MD2-015-005

Interaction between individual adrenal cortex sensitivity and insulin sensitivity in German Holsteins

Anja Schacht ^{1,*}, Lena Ruda ¹, Lea Fieguth ¹, Claudia Raschka ¹, Sven Dänicke ², Akos Kenez ³, Marion Schmicke ¹, Korinna Huber ³, Jürgen Rehage ¹

¹Clinic for Cattle, University of Veterinary Medicine Hannover, Foundation, Hannover, ²Institute of Animal Nutrition, Friedrich-Loeffler-Institute, Braunschweig, ³Department of Animal Science, University of Hohenheim, Stuttgart, Germany

Objectives: Subclinical ketosis mainly caused by negative energy balance and subsequent lipomobilisation is a frequent health disorder in dairy cows after parturition. Reduced insulin sensitivity commonly is seen as a promoting factor for excessive lipomobilisation. Furthermore, cows show considerable differences in their individual adrenal cortex sensitivity, leading to varying plasma cortisol levels as a reaction to stress. Cortisol, however, may contribute to decreased insulin sensitivity. The aim of this study was to evaluate the correlation between the individual adrenal cortex sensitivity and insulin sensitivity in dairy cows.

Materials and Methods: In our study an intravenous glucose tolerance test (GTT; 0.25 g glucose / kg bodyweight) followed by an insulin challenge (IC; 1 µg insulin / kg bodyweight) was performed on 20 multiparous German Holstein cows on day 106 postpartum. Blood was collected after glucose and insulin injection for 110 minutes in short term intervals to measure glucose and insulin concentrations. Three days later an ACTH (adrenocorticotrophic hormone) test was performed by injecting exogenous ACTH (80 µg / cow) and blood samples were taken for 120 minutes in short term intervals to assess cortisol levels. Furthermore, weekly from 42 days ante- until 106 days postpartum blood samples were collected from all cows for analysis of insulin, glucose and fatty acids (NEFA) to calculate surrogate indices of insulin sensitivity,

as follows: Quantitative insulin sensitivity check index (QUICKI) = (1/[log(Glucose (mg/dl)) + log(Insulin (µU/ml))]) and revised quantitative insulin sensitivity check index (RQUICKI) = (1/[log(Glucose (mg/dl)) + log(Insulin (µU/ml)) + log(NEFA(mmol/l))]). For statistical analysis base values, peak, nadir and area under the curve (AUC) were determined for ACTH test (cortisol), GTT (glucose, insulin), and IC (glucose, insulin). Also glucose elimination rate was calculated from GTT data. Results of the ACTH test were correlated (SPEARMAN) with results of the GTT and IC as well as with surrogate insulin sensitivity indices by means of the SAS computer package (Vers. 9.3).

Results: On day 106 after parturition results of the ACTH test (base value, peak, and AUC) revealed no significant (p > 0.05) correlations with QUICKI and RQUICKI. Base cortisol concentrations of the ACTH test correlated significantly with AUC glucose GTT (r = -0.45, p = 0.047) and nadir glucose IC (r = -0.49, p = 0.030) and peak ACTH test with nadir glucose IC (r = -0.51, p = 0.021). Peak and AUC cortisol ACTH correlated significantly with RQUICKI on d-7 (r=0.65, p = 0.002; r=0.46, p = 0.041, resp.) but not with QUICKI.

Conclusions: According to results individual adrenal cortex sensitivity appears to have only marginal effects on insulin sensitivity in dairy cows as measured by glucose tolerance test, insulin challenge and surrogate insulin sensitivity indices.

MD2-015-006

Periparturient immunosuppression and strategies to improve dairy cow health during the periparturient period

Josh Aleri ^{1,*}, Brad C. Hine ², Michael Pyman ¹, Peter Mansell ¹, Bill Wales ³, Bonnie Mallard ⁴, Andrew D. Fisher ¹

¹Faculty of Veterinary and Agricultural Sciences, University of Melbourne, Werribee, ²Agriculture Flagship, CSIRO, Armidale, NSW, ³Agriculture Research and Development Division, Department of Economic Development, Jobs, Transport and Resources, Ellinbank, Victoria, Australia, ⁴Department of Pathobiology, Ontario Veterinary College, University of Guelph, Ontario, Canada

Objectives: Selection for production traits with little or no emphasis on health and fitness traits has led to a higher incidence of disease in dairy cattle, including mastitis which is unfavourably genetically correlated with production traits. This increase in disease incidence is especially evident during the periparturient period when a temporary impairment in immune function (immunosuppression) occurs. In this review we aim to explore the causes of periparturient immunosuppression and propose short and long-term strategies aimed at improving dairy cow health and welfare during this critical period.

Materials and Methods: A systematic review on the causes of periparturient immunosuppression in dairy cattle coupled with their control strategies was reviewed based on literature search from 1980's to 2015. The methodology used was based on the protocol outlined by Sargeant et al., 2006. This involved specifying the research questions, a decision on the review process, criteria for the inclusion and exclusion of studies/literature, assessment of study quality, data extraction and synthesise. Literature was searched using the library discovery search engines of The University of Melbourne, University of Guelph and CSIRO. "PubMed" and "Google Scholar" searches were also used.

Results: A high proportion of cows experience immunosuppression during the periparturient period as a consequence of the physiological

demands of parturition, lactogenesis and colostrumogenesis. A focus on proper energy and nutritional balances during the periparturient period of dairy cows are important short-term strategies to improve the health and welfare of the transitioning cow. Research focusing on the arrest and reversal of the increased incidences of production-related health problems in the current modern dairy cow are incorporating immune responsiveness measures in selection and breeding programs. The development of methods to assess the immune competence phenotype of dairy cows has facilitated the adoption of selection and breeding programs aimed at improving general disease resistance of dairy herds. This approach has the potential to identify cows that are better able to cope with the challenges posed by their production environment whilst incorporating other health and survival traits. Immune response phenotyping, involves identification and selection of animals with an enhanced general immune responsiveness, as assessed by combining measures of an animal's ability to mount both antibody- and cell-mediated adaptive immune responses.

Conclusions: We propose a longer-term strategy based on improving the resilience of dairy herds through the selection of animals with enhanced resilience, and as a consequence, are better able to cope with the environmental challenges posed by their production environment.

MD2-015-007

Evaluation of sampling strategies for reticuloruminal pH measurements in individual cattle for the assessment of herd status

Nicholas Jonsson ^{1,*}, Matthew Denwood ², Malcolm Mitchell ³, Thomas Wittek ⁴, Joachim Kleen ⁵

¹Biodiversity Animal Health and Comparative Medicine, University of Glasgow, Glasgow, United Kingdom, ²Department of Large Animal Sciences, University of Copenhagen, Copenhagen, Denmark, ³SRUC, Edinburgh, United Kingdom, ⁴Department für Nutztiere und öffentliches Gesundheitswesen in der Veterinärmedizin, Veterinärmedizinische Universität Wien (Vetmeduni Vienna), Vienna, Austria, ⁵CowConsult.de, Uplengen, Germany

Objectives: Single time point or discontinuous measurement of reticuloruminal fluid pH has been used as a diagnostic tool to identify sub-acute rumen acidosis in lactating dairy cows, which is usually defined as 3 animals of 12 sampled with pH \leq 5.5. It is recommended that samples should be collected within 2-7 h after feeding. Our first objective was to use data from many intraruminal continuous pH monitoring boluses to determine the optimal sampling methodology. The second objective was to describe the variation in precision of estimation of pH values in a herd with the deployment of varying numbers of continuous pH monitoring boluses.

Materials and Methods: Continuously monitored reticuloruminal pH observations were obtained from devices deployed in clinically normal cattle on 13 German dairy farms and one British beef production research unit. Firstly, a single pH observation from within 15 minutes of a specified time of day was randomly sampled from each animal, ignoring the date on which the sample was taken. Then, a number of these animals were randomly sampled (without replacement) from the same farm, and the number of observations below the specified threshold was determined. A total of 10,000 iterations was used to give a probability estimate, and the whole process was repeated for each set of time of day, farm, threshold in the set {pH 5.0, pH 5.5, pH 5.8, pH 6.0}, number of sampled animals in the set {3, 4, 6, 12} and proportion of animals required to be below the threshold in the set {3/12, 1/3, 1/2}. To estimate the effect of number of

devices deployed for estimation of a herd's reticuloruminal pH status on the accuracy of the estimation, we used the continuous pH observations from the four farms with \geq 12 devices. A set of pH measurements taken from animals in the same herd at the same time and date was sampled with replacement from the available measurements. The absolute difference between the mean of the sample and the true mean of the observed pH from all animals at that date and time in that herd was recorded. A total of 1,000 iterations was used to give a mean absolute error for each combination of time of day, herd, and number of animals sampled.

Results: Reticuloruminal pH information was used from 111 cows in 16 herds, resulting in a total of 815,475 observations. The effect of herd (confounded by monitoring system) was highly significant ($p < 0.001$), with mean values being lowest in the British beef production unit during each time period.

There was a strong effect of time of day on the probability of detection of animals with pH values below specified thresholds, the probability of detection being consistently lower between 06:00 h and 14:00 h and higher between 18:00 h and 02:00 h. The pattern of diurnal rhythmicity differed among farms, being best described by a non-linear model with a single, double or triple sine-wave, broadly in line with frequency of offer of fresh feed.

To apply the accepted criterion of SARA of 3 from 12 animals sampled with pH \leq 5.5, for the beef herd on the transition diet, there was close to 100% probability that 3/12 animals would have a pH of equal to or below 5.5 between 18:00 h to 02:00 h, dropping to almost zero at midday.

The mean pH from a sample of 3 animals from herd A was within 0.1 pH units of the true mean 50% of the time, and within 0.25 pH units 99% of the time. In contrast the mean of a sample of 3 animals from herd N.3 was only within 0.25 pH units 50% of the time, and was within 0.8 pH units 99% of the time. Hence, the requisite number of boluses to be used for real-time monitoring purposes in any herd is dependent on both the inherent volatility in the herd as well as the desired level of accuracy.

Conclusions: Our study suggests that the currently accepted recommendation for the detection of SARA, as defined by a herd or group within a herd from which 3 of 12 randomly selected cows have a reticuloruminal pH (either by rumenocentesis or indwelling pH bolus) with a pH \leq 5.5, taken at a specified range of times after feeding is likely to be misleading in many instances, sensitivity being higher during the evening than daytime. The number of boluses required to provide an accurate representation of the true pH status of a herd varies with herd. Under stable nutritional conditions, as few as 3 boluses can provide an acceptable indication of herd status.

NHP-041-001

Surveillance 2014: A New Post Mortem Examination Service in the UKIngrid Den Uijl¹,*Jimmy Wiseman¹Roberto LaRagione¹Alasdair Cook¹¹University of Surrey, Guildford, United Kingdom

Objectives: In response to a review of animal health surveillance in England and Wales, a new system has been initiated that involves partnership between government, universities and private veterinary practices. The overall purpose is to provide early warning surveillance to identify new or re-emerging threats to animal and public health. The University of Surrey (UoS) is participating in this system by delivering a new model to perform surveillance post mortem examinations (PMEs) for several areas in England.

Materials and Methods: UoS in association with private veterinary surgeons, has recently started providing a subsidised surveillance PME service for the major farmed livestock species on behalf of Animal and Plant Health Agency (APHA). The service is delivered by UoS trained veterinary staff. The majority of PMEs will be conducted at new PME facilities at selected fallen stock sites around the country. The service commenced operation in February 2015 at Cowfold, West Sussex, and since then further sites have become operational in; Flagg, Derbyshire; Davidstow, Cornwall; Sutton Bonington, Leicestershire and Braintree, Essex.

All data and samples from these submission are managed by UoS. Farm and animal details as well as clinical history are collected and PME details are recorded in a purpose build digital system, PathPal™. Data collected from the PathPal™ system is exported to APHA to be merged for analysis of the national herd. The PathPal™ data is also analysed by the UoS. Maps are created to analyse the spread of disease, additionally an overview of the diagnoses made at PME are presented.

Results: During March-November 2015, 112 PMEs were submitted of which 61 were cattle, 31 sheep, eight birds, five pigs, three camelids, three goats and one deer. Some submissions consisted of multiple carcasses. The submissions were similar across all sites, with exception of Braintree, Essex, where submissions were lower than in the rest of the UoS allocated area.

In most cases a diagnosis was reached. Only 29% had a diagnosis not reached, however disease was localised to a particular body system in all but 4% of cases. Digestive, systemic and respiratory diseases made up 50% of our submitted caseload with circulatory, musculoskeletal and nervous disorders making up a further 30%, the remaining 20% were reproductive disorders.

Colisepticaemia was the most common diagnosis in neonates. In young cattle and sheep pneumonia was the most common diagnosis. Hepatic abscessation was the most common diagnosis in adult cattle. In adults sheep clostridial disease was often seen.

Conclusions: The study showed the possibility to carry out surveillance using PME facilities at fallen stock sites. In most cases a diagnosis was reached and some common diagnoses were presented. Further research using the automated data capture system will look into risk factors for common diagnoses and syndromic surveillance based on the collected data.

NHP-041-002

The Development Of 'Healthy Hooves', The Australian National Lameness Prevention ProgramJo Coombe^{1,2},*Erika Oakes²¹Faculty of Veterinary and Agricultural Sciences, University of Melbourne, ²Dairy Australia, Melbourne, Australia

Objectives: Dairy Australia is the national services body for dairy farmers and the industry in Australia. Unlike many other countries, Australia does not yet have a coordinated industry program to address lameness in dairy cows. In 2012, it became one of the key areas to be addressed by Dairy Australia. The objectives of "Healthy Hooves" are to promote animal welfare, industry sustainability and farm profitability through: a) establishment and adoption of a national lameness recording system, and b) improved management and prevention of lameness through the delivery of resources and training to farmers and their advisers.

Materials and Methods: The concept of a national program was developed in 2012 by bringing together many of the Australian key researchers, veterinarians, hoof trimmers and farmers for a stakeholder workshop. Since then, through the work of several steering groups, the framework of the 'Healthy Hooves' program has been put in place, with the target of a June 2016 launch. Key activities to achieve this target included 1) Resource development, including: a lameness investigation pack (aimed at advisors) and farmer resources (including lameness prevention guidelines, wall charts and booklets for lesion identification, data collection sheets and Standard Operating Procedures). 2) Updating of the farmer lameness workshop and development of webinars to upskill veterinarians or other industry trainers. 3) Video resources (a suite of videos that can be used for training and displayed on the Dairy Australia website). 4) Data activities (the development of a data capture tool) Performance of a full environmental scan of data capture in Australia and develop a platform that will allow farmers to capture lameness data quickly and easily, with agreement on an Australian industry approach to locomotion scoring.

Results: The resource development was completed as planned. The lameness prevention manual was written with the input of experts in the field, and will be edited for final publication. The lameness investigation pack is being piloted by several veterinarians prior to the launch of the program. Video resources were recorded with the input of a lameness expert from New Zealand, and the data capture tool is being developed with locomotion scoring based on the Dairy New Zealand 0-3 scale (0 being not lame, 3 being severely lame). Additionally the recording tool will have the ability to capture the most common lesions in the Australian pasture-based system. Webinars will be recorded by the launch date.

Conclusions: It is anticipated that following the launch of the Healthy Hooves project, there will be an increased awareness of lameness and farmers will have access to high quality resources to help them better manage it, with better methods to capture incidence. Additionally, it is hoped that using best practice guidelines, the development of an advisor base in Australia will enable farmers to access professional advice to manage the problem.

NHP-041-003

Quantifying the importance of Trojan dams in the national BVD eradication programme in IrelandFiona Reardon^{1,2},*David Graham³Tracy Clegg²Jamie Tratalos²Padraig O'Sullivan⁴Simon More²

¹Animal Health Ireland, CVERA, Cork, ²CVERA, Dublin, ³Animal Health Ireland, Carrick-on-Shannon, ⁴ICBF, Cork, Ireland

Objectives: A national eradication programme for bovine viral diarrhoea virus (BVDV) began in Ireland in 2013. To date, while Trojan dams are recognised as disseminators of infection, there is no published work quantifying how many persistently infected calves are born in herds due to the introduction of Trojan dams. Therefore, the objective of the current study was to quantify the importance of Trojan dams in relation both to the number of PI births directly attributable to them and the subset of herds where BVD introduction can be attributed to a Trojan dam.

Materials and Methods: The initial study population included all BVD+ calves born in Ireland in 2013 and 2014. Their dams were assigned a Trojan status based on birth date of the calf relative to the date that the dam entered the herd. A dam was considered to be a Possible Trojan if she entered the birth herd between days 30-120 of gestation (162-252 days before calving). For these animals, it was considered possible that infection had been contracted in either the birth herd or prior to entry. A dam was considered to be a Definite Trojan if she entered the birth herd after day 120 of gestation (less than 162 days before calving), having contracted infection prior to entering the birth herd. Herds with PI births were analysed by enterprise type, location, herd size and number of PI births. Dams of PI calves were analysed by age, parity, import status and number of movements during pregnancy. Source herd(s) were analysed by location, herd size and enterprise type. Data analyses were conducted using Microsoft Excel (Microsoft Corporation, Redmond, WA, USA) and STATA 14 (StataCorp LP, College Station, TX, USA).

Results: A total of 23,976 known PI calves were born in 11,960 herds in Ireland during 2013 and 2014. The percentage of PI births attributable to Trojan dams was relatively stable across regions, ranging from 7.5% of PI births in the South-West to 11.2% in the Midlands. A Possible or Definite Trojan dam was present on 10.5% of herds with at least one PI birth in 2013 and 2014.

The percentage of PI births attributable to Trojan dams was highest in dual purpose herds, accounting for 12.5% of all PIs. Beef herds had the highest absolute number of Trojans at 1,178, representing 10.8% of beef PI births.

40% of all dams of PI animals were first calvers. Of these first calvers 15% were Trojans, dropping to 6% in second parity dams. 19% of PI births to Trojan dams occurred where the dam had moved back into their herd of origin. In 71% of herds that had a Trojan birth, this represented the only PI calf born on that farm in that year.

Movement records were analysed of 1775 Possible and Definite Trojan dams. 46.7% of dams had only one movement, which was a direct farm to farm movement. 40.5% had at least one movement through a mart, making it difficult to categorically trace the source of infection.

Conclusions: This research highlights the contribution of Trojan dams to the birth of PI calves in Ireland. The high proportion (71%) of instances where the only PI birth on a farm in that year could be attributed to a Trojan dam highlights their role in the spread of infection. While testing of calves within days of birth allows the prompt identification of PI calves born to Trojan dams, these results confirm the need to address the issue on a systematic basis. Further research is underway to evaluate the effectiveness of potential control methods in minimizing Trojan movements.

NHP-041-004

A Novel National Animal Health And Welfare Programme For Dairy Farms

Mark Bryan ¹, *Shen-Yan Hea ²

¹Head of R&D, ²Epidemiologist, VetSouth Ltd, Southland, New Zealand

Objectives: The New Zealand dairy industry is the single most important export industry in New Zealand and by far the most economically important primary industry. However, it has lacked any form of national programmes incorporating disease monitoring or welfare assessment.

The Welfarm™ programme was developed to provide a national programme which monitors and benchmarks animal health, production and welfare, and which is of value to both the producer and to other stakeholders.

This presentation discusses the outcomes and challenges in a voluntary user-pays welfare based scheme.

Materials and Methods: The programme was developed by XLVets™ in New Zealand. A regional pilot programme was used as the basis for broadening into a national project. The project is now in its third year. Data is captured by veterinarians, from farmers themselves, through customer sales software, and via other electronic platforms, and is consolidated into a single online, benchmark dashboard.

The online data is updated in real time and provides vets and farmers with a view of their farm(s) with the regional and national average. The online platform has been developed to accommodate a large number of farms and measurements.

Data are collected from a range of areas which cover animal health, welfare and productivity. Therefore, body condition scoring (BCS), locomotion scoring and tail scoring are carried out. BCS is performed 4 times annually. Milk quality is benchmarked via bulk milk SCC, number of mastitis treatments and incidence of adverse milk grades. Reproductive data including non-pregnant rate and 6wk in-calf rate (ICR) are gathered. Other indices including mortality, calves reared, NSAID use, number of vet visits and antimicrobial use are also recorded and benchmarked.

Results: During the 2014/2015 season, data were collected via XLVets™ member clinics from 84,325 cows on over 150 farms nationally.

The mean annual mortality rate was 3.2% and the mean replacement rate was 26.6%. Mean herd size (cows wintered) was 613. The mean number of vet visits per year per 100 cows was 7.2, with a wide variation from 3- 9.8. This number was associated with herd size, such that the larger sized herds tended to have lower vet visits/100 cows.

Body condition showed a strong seasonal variation which accords with previous industry data. However, a regional variation was also detected, which may accord with feed quality and quantity in a largely pasture-based dairy system.

The largest proportion of antibiotic use was associated with dry cow therapy when measured using an animal daily dose (ADD) methodology but this was not the case when population corrected units (PCU) was used.

Conclusions: Although veterinarians and animal health experts recognise the value of maintaining efficient and appropriate welfare standards, one of the challenges with voluntary quality assurance programmes in a user-pays environment is developing value for the user.

The Welfarm™ programme has started the process of benchmarking animal health and welfare within New Zealand, and demonstrated that, for many indices, industry results are not necessarily where they would

be expected. It has provided the industry with quality benchmark data which can now be broadened into the further development of a national welfare programme.

NHP-041-005

Comparative assessment of surveillance programs to proof freedom of BHV1 in dairy herds in a disease-free and endemic situation.

Anouk Veldhuis ¹Inge Santman-Berends ¹Birgit Schauer ²Christoph Staubach ³Gerdien van Schaik ¹Frederick Waldeck ^{4,*}

¹GD Animal Health, Deventer, Netherlands, ²University Medicine Greifswald, ³Friedrich Loeffler Institut, Greifswald, Germany, ⁴GD Animal Healthcare, Deventer, Netherlands

Objectives: This study aimed at assessing the epidemiological performance of two surveillance systems for detecting bovine herpesvirus type 1 (BHV1) infection in dairy herds in the Netherlands as well as monitoring freedom from disease at herd level.

Materials and Methods: EU Decision 2004/558/EC and 2007/584/EC describe the requirements for cattle holdings to attain and maintain an official free BHV1-free status, which is the current basis for a country to obtain the Article 10 status as laid down in EU Directive 64/432/EC. Briefly, for dairy herds the requirements are (i) a test-and-cull procedure for all animals >9 months to obtain a free status, and (ii) yearly serology of all lactating cattle to maintain the free status. For this study, we designed an alternative surveillance system based on the voluntary BHV1 control system in the Netherlands. Basically, the program is based on (i) a test-and-cull procedure for all animals >12 months to attain the free status, (ii) monthly bulk milk testing to maintain the free status, and (iii) risk-based testing of purchased animals that originate from non-free herds. A scenario-tree analysis method was implemented to determine the sensitivity of the conventional (EU) and alternative (NL) surveillance system. To do so, the sensitivity of each surveillance system component for detecting a BHV1-infection at herd level (with an animal-level design prevalence of 10%) was calculated. Also, the probability of freedom at herd-level was estimated in time-steps with a 1-month interval, adjusted for the risk of introduction of BHV1 between tests. Analyses were carried out for a disease-free and an endemic country-level situation.

Results: Both systems reached a 100% sensitivity of the 'obtaining free status' component of the program. The sensitivity of the 'monitoring free status' component to classify a herd as positive when infected at an animal-level design prevalence of 10% was 100% for the conventional (EU) program and 96% for the alternative (NL) program. In an endemic situation, the EU program led to a probability of freedom of 99.6 - 100%, depending to the number of months since the yearly serological investigation of all lactating cattle. The alternative program led to a probability of freedom of 99.96 in months when no animals were purchased and 99.88% when animals from non-free herds were purchased. In a situation where the country is free from BHV1, both scenarios will lead to a constant probability of freedom of 99.9% or more. Additional and more detailed results will be presented at the conference.

Conclusions: This study presents the results of an epidemiological methodology that could be applied to compare surveillance strategies to proof disease freedom. The assessment of various surveillance designs can be highly useful to support decision-making towards a more risk-based approach of animal health surveillance.

NU-016-001

Inter-observer agreements on body condition scores and on the difference in body condition scores in dairy cows

Pierre-Alexandre Morin ^{1,*}Younes Chorfi ²Jocelyn Dubuc ¹Jean-Philippe Roy ¹Débora Santschi ³Simon Dufour ²

¹Département des sciences cliniques, ²Département de pathologie et de microbiologie, Faculté de médecine vétérinaire, Université de Montréal, Saint-Hyacinthe, ³Valacta, Ste-Anne-de-Bellevue, Canada

Objectives: The correlation between body condition score (BCS) and energy reserves, the ease and rapidity of scoring, and the relatively high intra and inter-observers repeatability make it a widely used herd management tool in bovine practice and in scientific studies. However, difference (loss or gain) in measurements of BCS (DMBCS) is generally more relevant when monitoring dairy cows. It remains unclear if DMBCS for a group of cows by several observers would provide a good agreement. Therefore, the objective of this study was to investigate the inter-observer agreements on BCS and on DMBCS in dairy cows.

Materials and Methods: A total of 73 Holstein cows from one commercial herd were conveniently enrolled in this observational study conducted between April and September 2015. After a short revision of the Ferguson BCS scale, three observers independently assessed BCS between 1 and 20 days in milk (early lactation; exam-1) and again between 41 and 60 days in milk (peak of milk production; exam-2). Each observer measured all cows at exam-1 and exam-2. At the second exam, observers were blinded to the BCS reported at first exam. Inter-observer agreement on BCS at exam-1 and exam-2 was computed using a quadratic weighted Kappa statistic (κ). For each observer, DMBCS between exam-1 and exam-2 were calculated. Using κ , inter-observer agreement on DMBCS was also determined.

Results: For exam-1, the median (lower quartile, upper quartile) of BCS was 3.0 (2.75, 3.25) for observer 3, and 3.25 (3.0, 3.25) for both observers 1 and 2. For exam-2, the median (lower quartile, upper quartile) of BCS was 3.0 (2.75, 3.25) for the three observers. The κ values for BCS measurements were 0.79 (95% CI: 0.69-0.85) and 0.84 (95% CI: 0.77-0.89) for exam-1 and exam-2, respectively. These results suggested a strong agreement between observers on single BCS measurements. The median (lower quartile, upper quartile) of DMBCS between exam-1 and exam-2 was 0.25 (0.0, 0.25) for observer 1, and 0.25 (0.0, 0.50) for both observers 2 and 3. These results suggested a slight loss of BCS over time in cows. When assessing agreement on DMBCS difference, a κ value of 0.49 (95% CI: 0.32-0.63) was obtained suggesting a moderate agreement between observers.

Conclusions: These results showed a lower agreement between observers when assessing DMBCS instead of independent BCS measurements. In this study, the median of DMBCS was 0.25 point and the range was relatively narrow (0.5). Therefore, such a small discrepancy between observers can still produce substantial disagreement. This finding suggests that multiple experienced observers could assess the BCS if only done once in scientific studies or in herds. However, in the same situations but using it to evaluate DMBCS (e.g. monitoring of the negative energy balance), assessment by one single observer would provide more reliable results.

NU-016-002

Identification of mycotoxin concentrations associated with disease and reproduction in dairy cows

Jocelyn Dubuc ^{1,*}Nacera Tazerout ¹Younès Chorfi ¹

¹Faculté de médecine vétérinaire, Université de Montréal, Saint-Hyacinthe, Québec, J2S 7C6, Canada

Objectives: Mycotoxins are biological compounds produced by microscopic fungi called molds. In the province of Québec (Canada), deoxynivalenol (DON) and zearalenon (ZEN) are the most prevalent mycotoxins in dairy cows feed. Acute intoxications with DON or ZEN are reported to have negative impacts on health and reproduction of dairy cows. However, data about the impacts of chronic low-dose intoxications of dairy cows with these mycotoxins are lacking. Therefore, the objective of this study was to identify DON and ZEN concentrations associated with disease or reproduction.

Materials and Methods: A prospective cohort study was conducted on 30 commercial dairy herds located in the vicinity of the bovine ambulatory clinic of the Faculté de médecine vétérinaire of the Université de Montréal (Saint-Hyacinthe, QC, Canada). A total of 360 dairy cows were enrolled in the study (12 cows per herd). Participating herds were conveniently selected based on their willingness to participate and on having computerized health and reproduction records. Herds were visited once by a research technician to collect feed, urine and blood samples (coccygeal vessels) from participating cows. These samples were tested for DON, ZEN, alpha-ZEN and beta-ZEN at the diagnostic laboratory of the Université de Montréal (Saint-Hyacinthe, QC, Canada). Cows were followed for 300 days after calving for disease occurrence and reproductive performance. Statistical analyses were performed using multivariable mixed logistic regression models.

Results: Cows fed ≥ 6.74 and ≥ 3.21 parts per million of DON were 4 and 2 times more likely, respectively, to abort and to have purulent vaginal discharge (clinical endometritis) than cows exposed to lower concentrations ($P < 0.01$). Cows with urinary concentration of beta-ZEN ≥ 6.23 parts per billion were 2 times more likely to be culled than cows exposed to lower concentrations ($P < 0.01$). Cows with urinary concentration of ZEN ≥ 2.70 parts per billion had 0.5 times the odds of conceiving at inseminations compared to cows with lower concentrations ($P < 0.01$).

Conclusions: Overall, these results suggest that feed and urinary concentration thresholds of DON and ZEN can be used to identify cows at high risk of disease and low risk of conception. These results should help farmers, veterinarians, and nutritionists to manage the impact of DON and ZEN in dairy cows.

NU-016-003

Trace element deficiencies related to production or health disorders in Belgian cattle herds

Emilie Knapp ^{1,*}Léonard Theron ¹Arnaud Sartelet ¹Anne-Sophie Rao ¹Vincent Frisée ¹Elodie Picard ¹Hugues Guyot ¹

¹Clinic Department of Animal Production, University of Liege, Liege, Belgium

Objectives: trace elements (TE) deficiencies impair health status of cattle herds and are described to be widely spread in Belgium. TE supplementation during winter is rarely accurately measured. During

pasture, TE supplementation is not systematically performed, especially for beef breeds or pregnant animals and heifers. The objective of this study was to bring out the TE status of dairy and beef herds visited for production, reproduction, mastitis or neonatal troubles, regardless TE supplementation. Furthermore, a comparison of the severity of TE deficiencies between years, seasons, speculations and agricultural regions was made.

Materials and Methods: From February 2014 to October 2015, blood sampling (heparin and plain tubes) were made in 110 cattle herds investigated for health or production disorders in Wallonia. In each farm, 7-10 clinically healthy animals, belonging to a specific and homogeneous group (production, heifers, pregnant), were sampled. Blood was centrifuged to harvest plasma and serum. Hemolyzed plasma/sera were discarded. To rule out the influence of an inflammatory process, the total proteins (TP) in both serum and plasma were measured using an electronic refractometer (EUROMEX®) and the fibrinogen concentration was so estimated. If suspicion of inflammation was present (difference between plasma TP and serum TP >6 g/L), the sample was also rejected. In order to limit costs of analysis, serum/plasma were pooled within a group/farm, so only one serum/plasma sample per group/farm was assayed. Determination of selenium (Se), zinc (Zn), Copper (Cu), iodine (I), vitamins (Vit) (A, E, B12) and haptoglobin concentration in plasma/serum was made in the laboratory (Collard-Synlab). Statistical evaluation, using average, standard deviation, proportion of deficient herds and t-Test, allowed the comparison of groups of production, speculation, year, season and agricultural regions regarding TE status.

Results: Se deficiency was the most represented as only 16% of herds were tested with an adequate Se status. The average Se concentration was $61 \pm 20 \mu\text{g/L}$ (mean \pm SD). In average, the blood Cu, Zn, and vitamin A/E/B12 concentrations were adequate. However, 22, 33 and 52% of the herds showed respectively an inadequate Cu, Vit B12 and Zn status. For Se status, there was a significant ($P < 0.05$) difference regarding the type of speculation with a higher level for the dairy compared to beef herds (Blood Se concentration of 64.0 ± 17.6 vs $55.4 \pm 24.3 \mu\text{g/L}$ and 17 vs 11% of herds with a good status). For Cu, the difference was also significant ($P < 0.05$) in favor of the dairy herds. Samples from cows in production (dairy and beef) had a significantly ($P < 0.05$) higher Se concentration than the non-productive animals (heifers and pregnant cows) (66 vs $51 \pm \dots \mu\text{g/L}$). In 2014, the global Se status was worse than in 2015 (57 ± 21 vs $66 \pm 20 \mu\text{g/L}$, $P < 0.05$) while Cu ($P < 0.01$), Zn ($P < 0.05$), I ($P < 0.05$), VitB12 ("trend" $P = 0.06$) and Vit A ($P < 0.05$) blood concentrations were lower in 2015 compared to 2014. Vit B12 deficiency was startling because normally ruminant is not subject to vit B deficiencies, however, in 2015 42% of the herds were deficient regardless of speculation and production. As vitamin B12 is related to rumen health and its bacterial activity, the hypothesis of better quality roughage ingested in 2014 was raised. Finally, a better selenium status ($P < 0.05$) was found during spring compared to autumn, probably due to the better distribution of mineral supplements during the winter period.

Conclusions: Despite massive information to farmers regarding TE importance and previous studies, it appears that Se deficiency remains quite important. Moreover, pregnant cows and heifers are more susceptible to these deficiencies. This results may be explained by insufficient TE recommendations for highly performant cattle such as Holstein or Belgian Blue cows, TE content allowed in mineral formulations, and the difficult economic situation in agriculture. TE status still need to be investigated in herds with production, reproduction or health problems, whatever the mineral supplementation occurring in the farm.

NU-016-004

Muscle function and muscle tissue phosphorus content in transiently phosphorus deprived dairy cows

Walter Gruenberg ^{1,*}, Peter Scherpenisse ², Paul Dobbelaar ³, Marie-José Idink ³, Inge Wijnberg ⁴

¹Clinic for Cattle, University of Veterinary Medicine Hannover, Foundation, 30173 Hannover, Germany, ²Institute for Risk Assessment Sciences, ³Dept. Farm Animal Health, ⁴Dept. Equine Sciences, Utrecht University, Utrecht, Netherlands

Objectives: The clinical relevance of hypophosphatemia that is commonly found in periparturient and anorectic cattle is uncertain but has empirically been associated with persistent recumbency in dairy cows. The objective of the present study was to determine if transient dietary phosphorus (P) deprivation of lactating dairy cows results in altered muscle function or muscle P metabolism.

Materials and Methods: Ten healthy multiparous, mid-lactating dairy cows received a ration with a P content of 0.18% over a period of 5 weeks that was followed by 2-weeks P supplementation phase. Blood, urine and muscle biopsy samples were collected regularly. Function of skeletal and heart muscles were evaluated regularly by electrocardiography and electromyography. Time effects were identified by repeated measures ANOVA.

Results: Dietary P deprivation resulted in the rapid development of marked hypophosphatemia. Lowest plasma [P_i] were measured after 9 days and were on average 60% below baseline. None of the animals developed clinical signs commonly associated with hypophosphatemia or any other health issues. Biochemical muscle tissue analysis showed that dietary P depletion and hypophosphatemia were not associated with a decline in muscle tissue P content. Electromyographic examination revealed increased occurrence of pathological spontaneous activity in striated muscles after 2 weeks of dietary P depletion in several cows, which could be suggestive of neuromuscular membrane instability.

Conclusions: These results suggest that muscle function was not grossly affected, although the increased occurrence of pathological spontaneous activity suggests that subclinical neuro-myopathy may have occurred. The results presented here furthermore indicate that plasma [P_i] is unsuitable to assess the muscle tissue P content in cattle.

Changes in the Fecal Microbiota of Beef Cattle Caused by Confinement and the Use of Virginiamycin as Growth Promoter.

José A. Bessegato ¹, Lais R. Paulino ¹, Julio A. Lisboa ¹, Amauri A. Alfieri ¹, Carlos H. Montemor ¹, Scott Weese ², Marcio Costa ^{1,*}

¹Universidade Estadual de Londrina, Brazil, Londrina, Brazil, ²University of Guelph, Guelph, Canada

Objectives: This study aimed to use high throughput sequencing to characterize longitudinal changes in the fecal microbiota of beef cattle from entrance to exit of a feedlot operation, as well as the consequences of virginiamycin used as Antibiotic Growth Promoter (AGP).

Materials and Methods: Thirty beef cattle entering a feedlot operation were randomly assigned into a treatment group receiving virginiamycin (ATB) for an estimated intake of 0.94 mg/kg/day, or into a control group

receiving the same diet without any antibiotic (CON). Fecal samples were collected at arrival, mid feedlot (25 days after arrival) and at exit to slaughter. The V4 region of the 16S rRNA gene was sequenced with an Illumina MiSeq platform. Bacterial membership (the different species composing the microbiota) and structure (bacterial composition and evenness of each species) were addressed respectively by the Classical Jaccard and the Yue and Clayton indices. A P-test was used to compare membership and structure found at each sampling time, and also for the comparison between groups (ATB vs. CON).

Results: Transition to confinement housing and management caused marked changes in membership and structure of fecal microbiota of beef cattle. At the phylum level, the comparison between arrival and mid feedlot revealed that entrance into the feedlot led to an increase of Firmicutes ($P=0.002$), Proteobacteria ($P=0.010$), Actinobacteria and Spirochetes and a decrease of Bacteroidetes, and Verrucomicrobia ($P<0.001$ for all comparisons). The use of virginiamycin significantly affected only bacterial membership, suggesting that changes mainly involved rare members of the community, and not the most abundant species present in the distal gut of feedlot cattle. At mid feedlot period, only Spirochaetes in ATB were significantly greater than in CON ($P<0.001$).

Conclusions: This study adds new insights to the understanding of microbial dynamics occurring due to changes in diet and the use of AGPs in feedlot cattle. The marked changes in composition and structure of fecal microbiota of feedlot cattle caused by change in management were characterized. The use of virginiamycin as AGP significantly affected membership of the fecal bacteria of beef cattle suggesting that the antibiotic has a stronger effect on the rare species present in that environment, but not on the most abundant species.

Phenotypic and Genetic variation of Liver Fluke Infection in Irish Cattle

Jennifer McClure^{1,*} Thierry Pabiou¹ Margaret Kelleher¹ John McCarthy¹ Catriona Scanlan¹ Andrew Cromie¹ Rebecca Carroll² Ross Evans¹

¹Irish Cattle Breeding Federation, Bandon, ²Animal Health Ireland, Carrick on Shannon, Ireland

Objectives: Infection with liver fluke is estimated to cost the Irish cattle industry between €70-90 million every year due to losses in milk and meat production and treatment of acute cases. Complications of infection with liver fluke can include: anaemia, secondary infections, cirrhosis, and sudden death. Due to its complicated lifecycle and resistance to environmental exposure, infection with liver fluke can be difficult to control in endemic areas and thus a genetic approach may be a viable alternative. The objective of this paper was to analyse the impact of liver fluke infection on carcass quality and estimate its heritability variance components.

Materials and Methods: The Irish Cattle Breeding Federation (ICBF) engaged two abattoirs with multiple factories around Ireland to pilot an automated data collection program for bovine liver fluke. In this process, veterinary inspectors recorded the incidence of live flukes in a liver, evidence of fluke activity in a liver-but no live flukes, or no fluke activity-past or present. These categories formed the basis of the phenotypic study while the genetic study used infected (past or present) and uninfected as a basis for the heritability estimate. The main edits applied to the dataset for genetic analysis were to include only animals of Holstein-Friesian origin, contemporary groups with some incidence of fluke infection and multiple sires and only animals with sires who had a minimum of 10 progeny distributed across a minimum of 2 herds. The edited dataset and pedigree contained 15,759 and 86,719 animals across 3 categories of animal slaughtered (steers: n = 8,532, young bulls: n = 1,588, cows: n = 5,639) respectively. Carcass information (carcass weight, conformation, and fat grading) was retrieved from the ICBF database for every animals kept. The genetic model applied to the data was a univariate animal model. Phenotypic data was analysed with MS Excel and SAS.

Results: Animals that were infected with fluke often performed worse than animals that were not infected with fluke. Those that were treated for fluke fell into the mid-range of these categories, as we would expect. On average, animals infected with liver fluke took longer to reach slaughter weight, had lower average daily gains, and had poorer carcass conformation than their contemporaries that were never infected with fluke. The heritability of liver fluke infection was 6% for steers, 5% for young bulls, and 2% for cows. Variability of the heritability increased when observing multiple breeds. This result will be investigated with further data on multiple breeds. Genetic correlations between the categories were positive (0.35 to 0.98) but not significant.

Conclusions: The objective of this paper was to analyse the impact of liver fluke infection on carcass quality and estimate its heritability variance components. Liver fluke infection has a negative effect on carcass quality. The heritability presented in this study showed that there is ample genetic variation to start engaging in a genetic program against liver fluke infection. An alternative strategy maybe to breed for resilience in these populations due to a number of infected animals performing as well or better than the uninfected animals, though more studies would have to be done with larger group sizes to ensure adequate power for the study.

PS1-042-002

A Fecal Egg Count Reduction Test With Cattle Treated 120 Days Earlier With Albendazole In Combination With Doramectin Or Extended Release Eprinomectin

T. A. Yazwinski^{1,*} C. A. Tucker¹ J. Powell¹ P. Beck¹ E. Wray¹ C. Weingartz¹ M. Andrews¹ L. Jones¹ J. Koltjes¹

¹Animal Science, University of Arkansas, Fayetteville, United States

Objectives: At present, cattle in the replacement and stocker phases of production in the USA commonly receive repeated anthelmintic treatments in an attempt by producers to maximize animal performance. As a consequence of this extensive anthelmintic usage, there has been widespread selection for resistance by most nematode parasite species that have a high incidence in younger animals. The current study was conducted to determine the anthelmintic efficacies of certain macrocyclic lactones in stocker cattle that had an immediate history of contrasting chemical intervention and parasite challenge.

Materials and Methods: A fecal egg count reduction test (FECRT) was conducted on naturally infected and heavily challenged Arkansas stocker cattle treated 120 days earlier with saline (S), doramectin in combination with albendazole (DA), or the extended-release formulation of eprinomectin (ER), and grazed by treatment group until the start of the FECRT. Animals within each of the prior groups were blocked by current fecal egg counts, and randomly allocated within each block to treatment with ivermectin, doramectin or moxidectin (all as injectables at 200 mcg/kg BW and with 29-30 animals per treatment group). At 16 days post-treatment, the animals were again fecal sampled for the post-treatment fecal egg count determinations. Additionally, coprocultures were conducted on all individual animal samples collected on days 0 and 16 wherein sufficient nematode eggs were present to allow for successful culturing and harvest. All data were obtained by personnel blinded to animal treatment. It should be noted however, that FECRT efficacies can be drastically divorced from true (control study) efficacies, and hence these data must be considered with that reservation.

Results: On day 0 of the FECRT, the arithmetic mean (SE), strongyle eggs per gram of feces (EPG) counts were 435(108), 561(134) and 341(67), for the ivermectin, doramectin and moxidectin treated cattle, respectively (P>0.94). Day 16 egg counts in the same order were 189(55), 334(98) and 27(15) (P>0.01). Using arithmetic means and by standard equation, the mean FECRT percentages were 56.5, 40.3 and 92.0 for ivermectin, doramectin and moxidectin, respectively. Mean, treatment group-specific FECRT percentages relative to prior experimental group for ivermectin, doramectin and moxidectin were 75, 67 and 95 (S group), 61, 44 and 86 (DA group) and 65, -58 and 92 (ER group), respectively. Coproculture larvae populations harvested on both days 0 and 16 of the FECRT study were *Haemonchus placei* > *Cooperia punctata* > *Oesophagostomum radiatum*, with trace levels of *C. oncophora*, *Trichostrongylus axei* and *Ostertagia ostertagi*. Coproculture, nematode populations were not seen to consistently vary with an animal's anthelmintic history or current parasiticide treatment.

Conclusions: Several observations can be drawn from these data; (1) that anthelmintic efficacies are significantly impacted by prior anthelmintic history, (2) that ivermectin and doramectin efficacies become more depressed than moxidectin efficacy in stocker cattle receiving extensive anthelmintic intervention and nematode challenge, and (3) assuming that 90% fecal egg count reductions are the minimum for an anthelmintic to be considered efficacious, most nematode parasitisms encountered in this study were left unchecked after animal treatment. These study data highlight a pressing concern relative to nematode control and productivity in cattle.

PS1-042-003

Use Of Fenbendazole Medicated Urea Molasses Blocks For Management Of Toxocara Vitulorum In Smallholder Large Ruminant Systems In Developing Countries

Peter Windsor ^{1,*}, Tereza Nemanic ¹, Sonevilay Nampanya ¹, Syseng Khounsy ², Russell Bush ¹ and Mekong Livestock Research Group

¹Faculty of Veterinary Science, University of Sydney, Camden, Australia, ²Department of Livestock and Fisheries, Luang Prabang, Lao People's Democratic Republic

Objectives: *Toxocara vitulorum* (Tv) is a major cause of calf morbidity and mortality in tropical smallholder large ruminant livestock systems, with anecdotal losses of up to 50% of calves in some countries. Although a single treatment of calves with pyrantel between 14 and 21 days following birth has high level efficacy against Tv, this strategy is poorly implemented when external projects cease. An alternative control strategy for Tv is required and the efficacy of treating post-parturient dams with medicated (containing fenbendazole; FBZ) medicated urea molasses blocks (MUMB) was examined.

Materials and Methods: Studies continue in the northern Lao Peoples Democratic Republic (Lao PDR) in 2015-16, following an initial pilot study involving cows (n=66) and calves aged <4 months (n=17), following a pre-treatment Tv prevalence in calves of 29.4% (established by faecal sample examination using a modified McMaster egg counting technique to examine for Tv and strongyle eggs). The effect of MUMB and non-medicated urea molasses blocks (UMB) on the cattle was evaluated through follow-up faecal collections on days 7, 18, and 28 of block supplementation of animals aged between 1 month and 10 years, with faecal egg count, body condition score (BCS), girth, coat texture and estimated price of large ruminants (AUD) recorded for individual animals at time of sampling.

Results: Large ruminant unweaned calves aged <4 months with access to MUMB demonstrated a reduction in mean Tv egg count from 190 eggs per gram (EPG) of faeces at pre-treatment to 0 EPG at day 7 of treatment. At conclusion of the pilot trial on day 28, MUMB and UMB supplementation demonstrated 100% and 95% reduction in large ruminant *T. vitulorum* egg burdens, respectively. From 7 days of block introduction, large ruminants with access to MUMB had a significantly lower (p<0.05) strongyle egg count (13.2 EPG) compared to animals exposed to UMB treatment (41 EPG), with animal accessing UMB supplementation displaying a continuous reduction in strongyle egg burden throughout the trial period. The mean large ruminant weight within both treatment groups increased throughout the trial, with a greater (p<0.001) weight associated with animals exposed to MUMB treatment, although BCS, coat texture and price demonstrated minimal or no change within this pilot study.

Conclusions: This pilot study demonstrates the potential efficacy of MUMB supplementation for control of Tv infection in large ruminant herds and may be more appropriate approach in developing countries than individual calf treatment with pyrantel. Studies are continuing and additional data on evaluation of the potential role of MUMB and UMB in Tv and strongyle parasite suppression will be presented.

Comments: This innovation may offer a more sustainable strategic parasite management strategy for countries where farmer knowledge of parasites is very poor and not easily addressed plus facilities for animal restraint for administration of therapeutics are largely non-existent.

PS1-042-004

Evaluation of a protocol of Paromomycin oral administration regarding the control of neonatal cryptosporidiosis in ruminants

Brigitte Duquesne ^{1,*}

¹Technical Managt, HUVEPHARMA, ANTWERP, Belgium

Objectives: The aim of the trials is to evaluate the efficacy in field conditions of a proposed protocol of Paromomycin oral administration regarding the control of neonatal cryptosporidiosis in calves, lambs and goat kids.

Cryptosporidiosis is a poorly controlled disease: no vaccine is available and there is only one molecule licensed for calves to date (Halocur™) with usage constraints. Published literature supports that Paromomycin has anti-protozoal properties and shows efficacy in the control of cryptosporidiosis in ruminants. Many studies nevertheless have been conducted under experimental infection and wide ranging doses have been recommended.

Materials and Methods: Trials are conducted in France in 3 different farms: a cattle operation, a sheep farm and a caprine holding during winter 2015.

The identified farms have had a history of neonatal scours caused by *Cryptosporidium* spp. with important losses. The attending veterinarian confirmed the diagnosis through faecal analysis by rapid tests in farm based on immunochromatography (Huve-Check®). In each operation, the diarrhoea occurrence determines date starting of the trial (Day 0)

24 animals born on date starting onwards are included in the study in each farm. The maximal interval between birth times of the animals is 48h for lambs and kids, one week for the calves.

They are divided into two groups (treated group and untreated): only males are included in the study, randomly and alternatively assigned to one group or another.

In each farm, the animals receive a dose of powder (Paromomycin sulfate in the treated group or Placebo in the untreated one) via the milk/milk replacer at 50mg/kg once a day (morning or evening, based on the farm regime) for 5 days, starting at 5th day after birth.

All animals enrolled in the experiment are monitored for a period of 28 days and the observations recorded : weight, faecal score 0-1 (absence or presence of diarrhoea), health score 0-1-2 (good, bad, very bad). Every week, starting from the first day of treatment, three faeces samples are taken to assess the presence of *Cryptosporidium* oocysts using flotation method, with an intensity scale (+, ++, +++)

Data analysis will be performed using IBM SPSS Statistics 21

Results: Expected Results

The selected criteria for assessing the efficacy of the protocol of treatment are the prevalence and the intensity of oocyst excretion, the presence of diarrhoea, the health rate status and weight gain.

The comparison of the results of faecal samples should show a different pattern of oocysts excretion between treated and untreated animals. In order to determine possibly differences depending on species, the oocysts excretion curves will also be compared for calves, lambs, goat kids.

For each species, the effectiveness of the treatment will be assess by comparison with the control group of the rate of morbidity and/or mortality, the occurrence and duration of diarrhoea episodes and the evolution according to the age of the animals , the prevalence of clinical signs and level of health score, the improved daily weight gain.

Conclusions: Due to the high resistance of *Cryptosporidium* against a lot of disinfectants and environmental influences, additional appropriate measures should be taken to reduce the prevalence of cryptosporidiosis

If determined to be effective in the study, the protocol of oral administration of a daily dose of 50mg Paromomycin sulfate /kg body weight from the 5th day to the 10th day after birth should allow to control cryptosporidiosis.

This reasonable use of Paromomycin could be recommended in farms experiencing cryptosporidiosis in order to reduce economic losses, environmental contamination and the risks for animal and human health.

Comments: On-going field trials during winter 2015. Reason for which results are "expected" and figures not yet shown.

PS1-042-005

Best practice liver fluke control using synergistic flukicides

Glenn Anderson^{1,2,3,*}; Terry Spithill²; Nick Sangster³; Gareth Kelly⁴; Joe Boray⁵

¹Virbac, Sydney, ²Department of Animal, Plant and Soil Sciences, LaTrobe University, Melbourne, ³School of Animal and Veterinary Sciences, Charles Sturt University, Wagga Wagga, ⁴School of Environmental and Rural Science, University of New England, Armidale, ⁵Sydney, Australia

Objectives: Treatment of liver flukes (*Fasciola hepatica*) has been relatively effective since triclobandazole became available in the 1980s, but Boray demonstrated that combinations of actives could provide even better efficacy through truly synergistic interactions. Two such combinations, triclobandazole + oxfendazole (Flukazole® C) and nitroxylinil + clorsulon [+ivermectin] (Nitromec® Injection) are available commercially in Australia. The objectives of this work were to determine if the superior efficacy displayed by these synergistic flukicides provides real benefits to livestock producers through better productivity and improved resistance management.

Materials and Methods: Productivity Trials – Young beef cattle (about 9 months old) naturally infected with liver flukes were randomly allocated to groups (n=20-22 per group), individually weighed and then treated according to label instructions with one of the synergistic products or the producer's normal fluke treatment. Case study 1 included triclobandazole (Fasinex®) and triclobandazole + oxfendazole (Flukazole® C) while Case study 2 included triclobandazole + abamectin (Genesis® Ultra Pour-on), triclobandazole + oxfendazole (Flukazole® C) and nitroxylinil + clorsulon [+ivermectin] (Nitromec® Injection). All groups received roundworm treatment via the macrocyclic lactone (ML) component of the product or an additional ML treatment (Cydectin® pour-on). An additional triclobandazole + oxfendazole group was treated with a long-acting ML product (Cydectin® LA Injection) to compare the relative impacts of fluke and roundworm control. Fluke egg counts and liveweight gains were then monitored for about 4 months (3 or 4 time points), with the animals being managed as they would normally.

Resistance assessment (Case study 3) – Animals proven to be infected with liver flukes using faecal egg counts were allocated randomly to groups of 15, individually weighed and then either treated according to label instructions with one of three products, triclobandazole (Fasinex®), triclobandazole + oxfendazole (Flukazole® C) or nitroxylinil + clorsulon [+ivermectin] Nitromec® Injection, or left untreated (control). Fluke egg counts were performed on Days 0 and 28 as an indicator of reduction in fluke burdens.

Results: Case study 1 – Fluke egg counts were reduced to zero in all animals and remained that way throughout the trial period. Despite that, animals treated with the triclobandazole + oxfendazole combination gained weight faster than those receiving triclobandazole alone. At 135 days after treatment an average weight advantage of 8kg (liveweight gain of 52kg vs 44kg) was observed (P<0.05). In comparison, an extra 13kg in liveweight gain was achieved by including better roundworm control.

Case Study 2 – Fluke eggs were detected in the faeces of animals in the pour-on group at Day 71 whereas eggs were detected in the triclobandazole + oxfendazole group at Day 139 and the injection group remained at zero throughout. In this case the synergised flukicides provided a weight gain advantage of 11-12 kg (54kg and 55kg vs 43kg) (P<0.10) while better roundworm control provided a benefit of 7kg.

Case study 3 – Fluke egg counts remained high in the control group (11.9 eggs/10g at Day 28). While the number of animals positive by egg count in the group treated with triclobandazole alone was lower than that in the control group, the mean egg count in the positive animals was higher than the control group (13.1 eggs/10g). While the triclobandazole + oxfendazole treatment was not fully effective, that group had even fewer animals testing positive and the mean egg count in positive animals was low (3.5 eggs/10g). In contrast, the nitroxylinil + clorsulon treatment was highly effective (only 1 egg detected in one animal).

Conclusions: Synergistic flukicides can provide substantial productivity benefits to livestock producers and could also play an important role in managing triclobandazole resistance. While no triclobandazole-based product could be recommended for use against resistant flukes, the principle of using the highest potency products to minimise selection for resistance via 'head selection' suggests that combinations should be integral in preventative programs. The nitroxylinil + clorsulon combination offers a highly efficacious alternative for use in rotational programs to slow the onset of resistance or to overcome flukes already resistant to triclobandazole.

PS1-042-006

Acquired immunity towards digestive strongyles in 2nd grazing season dairy heifers not dewormed with macrocyclic lactones during the previous winter

Philippe Camuset^{1,*}

¹Cabinet vétérinaire, 76190 Yvetot, France

Objectives: The aim of the study is to demonstrate that the absence of deworming at housing with an antiparasitic macrolide allows, during the winter period, the accomplishment of immunity towards digestive strongyles (GIS) in dairy heifers during their second grazing season. Such a strategy allows heifers to meet a complete immunity towards fourth stages and adults worms of GIS during the winter. So, it will not be necessary to deworm them during the second grazing season. The next antiparasitic treatment will usually take place at calving.

Materials and Methods: Six herds (1 in 2014, 5 in 2015) were selected because they were followed up according to parasitology audit design in our practice; that consists in a quality approach aiming to assess and manage as precisely as possible the parasitic risk.

Data regarding the first grazing season were available (pasture management, anthelmintic treatments). Those herds were implementing preventive treatments (long acting or pour-on moxidectin, oxfendazole boluses).

In those herds, blood pepsinogen have been measured at the end of the first grazing season according to the French method, allowing us to determine the best choice of anthelmintic housing treatment. None was advised for 4 herds and oral fenbendazole for 2.

During the second grazing season, fecal egg counts were performed 10 to 16 weeks after turn out using a Mc Master method with a sensitivity of approximately 10 epg (egg per gram of faeces) ; 5 heifers were investigated within 5 herds, 3 within the last one.

Results: Among the 28 investigated heifers, 21 were not shedding any eggs, the remaining seven were shedding between 10 and 20 epg. The detailed results for each herd are the followings:

Houdetot (2014) : 1st grazing season (GS), 2 batches turned out mid-April & mid-May (long-acting [LA] moxidectin (mox.) at beginning of April. Housed mid-November; 7 Pepsinogen **Results:** 420 > 821 ; no treatment. 2nd GS, turn out at beginning of April, full grass, FEC: 0, 0, 0, 10, 18

Bréant (2015) : 1st GS, 2 batches turned out mid-april (oxfendazole bolus) & mid-august (LA mox.). Housed beginning of November; no Pepsinogen results ; no treatment. 2nd GS, turn out beginning of May, two plots with fortnight movement, FEC: 5 negatives

Eudier (2015) : 1st GS, 2 batches turned out mid-April (LA mox.) & mid-June (pour-on mox.). Housed at the end of November; 5 Pepsinogen: average 1063 (475 > 2085); Fenbendazole per os. 2nd GS, turn out beginning of April, full grass, FEC: 0, 0, 0, 0, 18

B. Leber (2015) : 1st GS, turn out on April or May, LA mox. at the end of March. Housed 20th November; 5 Pepsinogen: average 1170 (586 > 1852); no treatment. 2nd GS, turn out 20th April, full grass, FEC: 3 negatives

Chêne (2015) : 1st GS, LA or pour-on mox. according to the time of turnout. Housed end of November; 7 Pepsinogen: average 1130 (656 > 1376) ; Fenbendazole per os. 2nd GS, turn out at the beginning of April, full grass, FEC: 0, 0, 0, 13, 17

Houdetot (2015) : 1st GS, same management as 2014. 4 Pepsinogen: 597 > 646 ; no treatment. 2nd GS, same management as 2014; FEC 2nd GS: 0, 0, 0, 10, 20

Conclusions: The absence of GIS egg shedding during the second grazing season in not winter dewormed heifers is a good indicator of the acquired immunity toward those parasites. It gives a good assessment of the parasitic challenge met by the animals.

The most important conclusion consists in the fact that a sustainable management of the 1st grazing season GIS infestation allows to drastically reduce the use of anthelmintic treatments during the 2nd grazing season with compromising an optimal growth and first calving size.

PS2-043-001

Can we control nematodes more efficiently in suckler beef herds using targeted selective treatments?

James O'Shaughnessy ¹, *Bernadette Earley ² John F. Mee ³ Michael L. Doherty ¹ Paul Crosson ⁴ Damien Barrett ⁵ Theo de Waal ¹

¹School of Veterinary Medicine, UCD, Dublin, ²Animal and Bioscience Research Department, Teagasc, Co. Meath, ³Animal and Bioscience Research Department, Teagasc, Co. Cork, ⁴Livestock Systems Department, Teagasc, Co. Meath, ⁵Sligo Regional Veterinary Laboratory, Department of Agriculture, Food and the Marine, Co. Sligo, Ireland

Objectives: With the emergence of anthelmintic resistance (AR) in cattle nematode populations, there is a need to reassess our currently employed approaches to nematode control in cattle. One potential solution is to focus on treatment of the individual animal using targeted selective treatments (TSTs). This study reports on the use of a TST-based approach to nematode control in suckler beef calves over their first grazing season (FGS). The objective was to determine the minimum number of anthelmintic treatments needed to control infections due to both *Dictyocaulus viviparus* (lungworm) and *Ostertagia ostertagi* in FGS suckler beef calves.

Materials and Methods: Ninety nine beef calves with an initial mean age (s.d.) and mean live weight (s.d.) on June 28th (day 0) of 107 (23.1) days and 160 (32.5) kg, respectively, from a spring-calving beef herd were used in this study. Calves with their dams were randomised to one of two treatments; 1), standard treatment (positive control) (n = 25; × 2) and 2), TST (n = 25; × 1 and n = 24; × 1) based on calf age, weight, sex, dam breed and sire breed. Control and TST calves and their dams were rotationally grazed in adjacent paddocks. The study commenced on day 0 and finished on day 124. Every three weeks calves were weighed and blood and faecal sampled. Faecal samples were analysed for the presence of lungworm larvae using a modified Baermann technique and faecal egg counts (FEC) were determined using a modified McMaster method. Plasma pepsinogen concentrations (PP) were also measured while blood samples collected from calves on days 0 and 124 were tested for the presence of antibodies to lungworm using an enzyme-linked immunosorbent assay (ELISA). All calves in the control groups were treated subcutaneously with ivermectin on days 0, 41 and 82 while all calves (both control and TST) were treated with ivermectin on day 124. Individual calves in the TST groups were treated with ivermectin based on their laboratory results as follows; 1), a positive Baermann result or 2), a positive/negative Baermann result with PP ≥ 2 international units of tyrosine per litre and FEC ≥ 200 eggs per gram of faeces. Data were analysed using the PROC MIXED function of SAS (Version 9.3, SAS Institute, Cary, NC).

Results: Apart from the pre-housing treatment, no calves in the TST groups were treated at pasture. The overall average daily live weight gain (P = 0.17) for control and TST groups was 0.89 (± 0.02 SEM) kg/day and 0.94 (± 0.02 SEM) kg/day, respectively. There was an effect of time (P = 0.005), treatment (P < 0.001) and a treatment × time interaction (P = 0.004) for FEC. There was an effect of time (P < 0.001), a treatment × time interaction (P < 0.001) and no effect of treatment (P = 0.535) for PP. With an optical density ratio ≥ 0.5 indicating infection with adult lungworm, three calves (two control and one TST) were seropositive on day 0. This was in contrast to day 124 when 28 calves (18 TST and 10 control) were seropositive despite no calves having lungworm larvae identified in their faeces during the course of the study.

Conclusions: Nematode challenge can potentially be controlled with minimal anthelmintic treatments in FGS suckler beef calves at pasture whilst not significantly impairing performance. In addition, although suckler beef calves at pasture do get exposed to lungworm challenge in the FGS, this appears to occur at low levels as judged by the differences in results between the ELISA and the modified Baermann technique.

PS2-043-002

Detection of acute *Tritrichomonas foetus* infection in beef cows and bulls

Jeff Ondrak ¹, *Katherine J. Whitman ¹ Dale M. Grotelueschen ¹

¹Great Plains Veterinary Educational Center, University of Nebraska-Lincoln, Clay Center, NE 68933, United States

Objectives: *Trichostrongylus axei* causes a highly contagious venereal disease of cattle worldwide whose control relies on detection of infected bulls. The purpose of this study was to examine the detection of early infections in cows and bulls.

Materials and Methods: Eight *T. axei* negative cows were bred by an infected bull. Post exposure vaginal samples were collected daily for one week, then twice in a week, and then once weekly for five weeks. Eight *T. axei* test negative bulls bred an infected cow and preputial samples were collected on days 1, 2, 3, 4, 5, 6, 7, 14, 19, 22, and 25 post exposure.

Samples were incubated for 4 days with daily microscopic examination followed by polymerase chain reaction testing.

A spreadsheet calculated the descriptive statistics.

Results: Eight cows became infected with median and mean days to initial diagnosis of 4 and 7.8 days, respectively and median and mean days to continuous positive tests of 10.5 and 11.9 days, respectively. Days to initial detection in cows ranged from 1 and 28 days.

Three bulls became infected with median and mean days to initial diagnosis of 4, 3.7 days, respectively and median and mean days to continuous positive tests of 19 and 17.9 days, respectively. Days to initial detection in bulls ranged from 1 and 4 days.

Conclusions: Testing acutely infected cows may provide early detection of herd infections. Acutely infected bulls generate positive tests, but may require more than 2 weeks of sexual rest for consistent test positivity.

Comments: This abstract is less than 250 words to protect future publication options for the full manuscript. Unfortunately this makes it extremely brief.

PS2-043-003

The development and application of a protocol to identify biases in papers on abattoir surveys of *Fasciola hepatica* infection in ruminants

R. Carroll ¹, *A. Forbes ², D.A. Graham ¹, L. Messam ³

¹Animal Health Ireland, Carrick-on-Shannon, Co. Leitrim, Ireland,

²School of Veterinary Medicine, Glasgow University, Glasgow, United Kingdom, ³School of Veterinary Medicine, University College Dublin, Dublin, Ireland

Objectives: *Fasciola hepatica* is a parasite of clinical and economic importance in ruminants worldwide and in parts of the world is also an important zoonotic pathogen. Abattoir surveys are often used to estimate the prevalence of *F. hepatica* in ruminants because they allow researchers to inexpensively study large samples. Nevertheless, prevalence estimates from these surveys can be affected by both selection and information biases. The aim of this project was to develop and apply a protocol, to recently published papers on abattoir surveys of *F. hepatica*, in order to determine the extent to which these biases were taken into consideration.

Materials and Methods: We first developed a series of questions aimed at determining if selection and/or information bias are present in published abattoir surveys. The questions were developed as a flow chart and aimed to analyse whether the sample in the abattoir reflected the population to which inferences are being made, whether the movement history of the animals is discussed and whether the paper adequately outlines the procedure used to determine *F. hepatica* infection. Papers

for analysis were selected by conducting a literature review in PubMed. Search terms used were "liver fluke and abattoir and prevalence" with the terms present in either the title or the abstract. We included papers published between January 2005 and January 2015 in our study, giving 28 papers for review. Papers were further excluded for the following reasons: the main focus was on other parasite species (7), prevalence was not discussed (4), the paper was not available in English (4), or at all (1). We then applied the questions, in the form of a flow chart, to the remaining 12 papers to check for the presence of selection and/or information bias.

Results: The flow chart protocol made the procedure for applying questions to papers a streamlined and systematic process. The questions posed identified that the population to which inferences were made was thoroughly discussed in 2 papers, there was limited discussion in 9 papers and it was not discussed in 1 paper. The geographic location of the abattoirs was described in all papers and the location from which the animal population was derived was discussed to some extent in 4 papers. The implication in other papers (8) was that the abattoir population of cattle was derived from the region surrounding the abattoir but this was not stated explicitly. The movement history of the animals was not discussed in any of the papers reviewed. The procedure used to determine the infection status of livers was thoroughly described in 7 of the 12 papers reviewed while one paper did not describe the procedure at all. Eight papers did not report the sensitivity or specificity of the test. Two papers briefly discussed the sensitivity of meat inspection for diagnosing *F. hepatica* but did not quantify it and 2 papers considered the techniques they used to be a gold standard for diagnosing *F. hepatica*.

Conclusions: The questions posed in our study identified that most papers did not adequately consider the potential for selection or information bias. Given that the validity of prevalence estimates are determined by the magnitude of these biases, it is prudent to consider their presence in an abattoir survey. While a final verdict on their extent may be a matter of judgement, they still need to be taken into consideration. A systematic method, such as a flow chart-as used here, would allow researchers to identify potential biases in abattoir data. Readers should also consider if papers resulting from such data adequately deal with the subject of bias.

PS2-043-004

Alternative Interpretations of English Faecal Egg Count Reduction Test (FECRT) Data

Ian Nanjiani ¹, *Hannah Lester ¹, Lindsay Heasman ¹, David Burden ², Mike Taylor ³, Tim Potter ¹, Johnathan Love ⁴, Louise Kelly ⁴, Chris Robertson ⁴

¹Research, Westpoint Veterinary Group, Warnham, ²Duillio, Gloucester,

³VParST, Market Weighton, ⁴Department of Mathematics and Statistics, Strathclyde University, Glasgow, United Kingdom

Objectives: Anthelmintic (field) efficacy in cattle is most commonly assessed using the (unvalidated) Faecal Egg Count Reduction Test (FECRT). FECRT outcome is influenced by group size, pre-treatment faecal egg count (FEC) and FEC sensitivity. Current WAAVP guidelines don't take full account of these or other factors (such as incorrect dosing or sample handling) risking falsely identifying Efficacy or Lack of Efficacy (LOE, which the current guidelines classify as anthelmintic resistance). Here, two expert systems were designed to aid interpretation of FECRT data sets to reduce the likelihood of misclassifying FECRT results as "LOE" or "Resistance".

Materials and Methods: FEC data from 88 FECRTs conducted in

first-season animals in geographically distinct English regions between 2012 and 2014 were analysed by calculating percentage reductions in egg counts using pre- and post-treatment group arithmetic mean FEC, and 95% confidence intervals (CI) were constructed. The efficacy of macrocyclic lactones (ivermectin and doramectin pour-on & injectable) and fenbendazole (drench) were assessed. The classification of FECRT results using adapted WAAVP thresholds (i.e. efficacy $\geq 95\%$ and lower 95% CI $\geq 90\%$ indicating acceptable anthelmintic efficacy), were compared to the evaluation of the same FECRT data using two unvalidated expert systems based on published literature and personal experience. Expert system 1 (ES1) considers treatment group size, the group mean Day 0 and Day 14 FEC, and the distribution of egg counts. Expert system 2 (ES2), in addition to the criteria applied using ES1, considers the width of the 95% confidence intervals, the larval culture data and the season in which the FECRT was conducted.

Results: When applying WAAVP criteria, 28.4% of groups were classified as efficacious and 71.6% were classified as lack of efficacy (LOE). When ES1 was applied, the percentage of FECRT classified as efficacious and LOE decreased to 8 and 9.1% respectively and 83% were classified as inconclusive. When ES2 was applied, 20.5% of the FECRT results were classified as efficacious, 20.5% as LOE, 25% as suspected (S)LOE and 34.1% as inconclusive. Using WAAVP criteria, 25 groups were classified as efficacious and of these, ES1 categorised 7 as efficacious and 18 as inconclusive, while ES2 categorised 16 as efficacious, 2 as (S)LOE and 7 as Inconclusive (INC). WAAVP criteria classified 63 groups as LOE. Using ES1, 8 were LOE and 55 were inconclusive. Using ES2, 2 groups were efficacious, 19 SLOE, 19 LOE and 30 INC.

Conclusions: Many WAAVP "LOE/Resistance" results were inconclusive when expert systems were applied. ES1 produced more inconclusive results than ES2, suggesting the extra criteria included in ES2 aid the interpretation of FECRT results, reducing the number of inconclusive results. Misclassification of product efficacy may occur if estimates do not take into account eg treatment group size, pre-treatment mean FEC, etc. These unvalidated "Expert Systems" provided a more "granular" assessment of "LOE", allowing apparent LOE to be differentiated from farms with less conclusive evidence, something "standard" WAAVP interpretation did not allow.

PS2-043-005

Six-year longitudinal study of *Fasciola hepatica* bulk milk ELISA testing in Irish dairy herds

Maria P. Munita^{1,*}, Rosemary Rea², Ana Martinez-Ibeas¹, Noel Byrne¹, Riona Sayers¹

¹Animal & Biosciences, Teagasc, Moorepark, Fermoy, Co. Cork,

²Biological Sciences, Cork Institute of Technology, Cork, Ireland

Objectives: Risk factors associated with *Fasciola hepatica* (liver fluke), one of the most important helminth parasites of ruminants, include high levels of rainfall and temperatures in excess of 10°C. Ireland's weather, therefore, provides ideal climatic conditions under which liver fluke can thrive. Previous studies have highlighted that seasonal variations in liver fluke herd prevalence occur in Ireland. The objective of the current study was to investigate the extent of any annual variation in *F. hepatica* bulk milk ELISA results and examine the correlation between liver fluke bulk milk seropositivity and soil temperature and rainfall.

Materials and Methods: A total of 32 herds participated in the study from March 2009 to December 2014. Of these 22 were commercial farms located in the Munster province of Ireland (southern-western

region). The remaining 10 herds were research farms managed by Teagasc (Irish Agriculture and Food Development Authority). Bulk tank milk (BTM) samples were submitted by each farm on a monthly basis. Samples were collected into standardised kits provided to each farmer. All BTM samples were preserved using broad spectrum microtabs II and received for testing within 48 hours of sampling. A commercially available ELISA kit (Ildana Biotech, Dublin, Ireland) was used to test all samples and has a sensitivity [Se] and specificity [Sp] of 98%. This kit uses a recombinant mutant Cathepsin L1 antigen (CL1), the immunodominant protease found in *F. hepatica*. Each test was completed according to kit manufacturer's instructions and a positive cut-off of 15 S/P was used for herd classification as positive (Pos) or negative (Neg). BTM data from October of each year were used for the current analysis. Rainfall and soil temperature data were obtained from the weather measurement station located in Teagasc, Moorepark, Co Cork. Scatter plots (mean S/P vs. rainfall and mean S/P vs. temperature) and R2 values were generated in MS Excel (2010).

Results: A total of 1420 samples from 32 herds was analysed in total. The mean number of samples received per farm per year was seven. The number of herds submitting October samples in each year of the study, the proportion of herds recording positive BTMs and the mean rainfall and temperature for October in each year are outlined in the following table.

	n	% Pos	Mean S/P	Rainfall	Temp
Year 1	29	65.5	105.9	126.7	12.8
Year 2	28	75.0	107.1	82.6	11.0
Year 3	28	67.9	73.4	83.3	12.1
Year 4	27	77.8	64.3	99.3	10.1
Year 5	26	65.4	56.9	150.4	8.6
Year 6	25	60.0	43.9	153.6	12.4

A poor correlation existed between BTM ELISA and rainfall ($R^2=0.3$) and soil temperature ($R^2=0.09$). It should also be noted that the relationship between rainfall and BTM results was unexpected, as ELISA readings decreased with increasing rainfall.

Conclusions: Although the proportion of herds classified as positive remained relatively static over the course of the study, BTM ELISA readings decreased steadily. The lack of an acceptable correlation between rainfall, soil temperature and liver fluke BTM ELISA would suggest that the decreasing BTM fluke results are due to improved liver fluke control on Irish dairy farms.

PT1-039-001

The practical implementation of a risk based Johne's Disease management programme on large dairy herds

Richard Sibley ^{1,*}, Peter Orpin ²¹West Ridge Veterinary Practice, Witheridge, ²Park Vet Group, Leicester, United Kingdom

Objectives: This paper will describe the implementation of a Johne's Disease management programme on three different large dairy herds that opted to use a risk management strategy to control endemic Johne's disease. The study considers the reasons for the selections of the use of quarterly milk testing and the management of high risk cows to prevent new infections, and the specific husbandry practices that were implemented to prevent disease spread. Issues with compliance with the Johne's Disease management plan will be discussed, and specific components of the plan that were particularly difficult to implement will be highlighted.

Materials and Methods: Three large dairy herds (650 cows, 320 cow and 180 cows) were engaged with Johne's Disease surveillance and management as part of a regional paratuberculosis awareness campaign. Each farm had a risk assessment to quantify the risks of Johne's Disease entering the herd and spreading within the herd using a web based herd health management tool (myhealthyherd.com.)

Once biosecurity and biocontainment risks had been quantified, the current prevalence of Johne's disease within each herd was estimated by a targeted 30 cow screen, and a future predicted prevalence estimated to help with the choice of control strategy. Each farm opted for a risk based management strategy using quarterly milk antibody elisa testing to identify high risk cows that were likely to be shedding *Mycobacterium avium* paratuberculosis (MAP), and infectious cows were managed to prevent the spread of infection to susceptible young stock

Results: A specific risk management strategy was formulated for each farm to minimise the risk of MAP transferring from infected, infectious cows to susceptible young stock. The plan was created using the known risks identified in the risk assessment, and the practicality of implementing effective husbandry changes that would prevent new infections. The robustness of the plan was tested against a model within the health management system to ensure that there was a high likelihood of success.

Each of the farms found the implementation of the plan challenging. The control of spread was particularly challenging for the herds with large numbers of cows calving in limited calving yards or calving accommodation during the winter months. There were also issues with compliance with milk and colostrum separation and pasteurisation, with several instances of post pasteurisation contamination leading to potential spread of disease. The level of compliance reflected the success of Johne's Disease control, with poor compliance being revealed by first lactation heifers testing positive by milk elisa tests some three years after the implementation of the plan. In one herd the number of test positive first lactation heifers fell from 7.7% to 2%, and in another, it rose from 3.4% to 4.3% over 3-4 years. All herds managed to significantly reduce the prevalence of Johne's Disease compared to the prediction of prevalence at the outset, but none have managed to eradicate the disease completely.

Conclusions: Each of the three farms had significant prevalence of Johne's Disease present in the dairy herds at the start of the programme. Predicted prevalence in all three herds was high due to the high risks of spread inherent with their husbandry practices which was revealed in the risk assessment conducted at the outset. The study demonstrates that risk based control strategies are effective at controlling Johne's Disease in large dairy herds, but the effectiveness of the control measures is

dependent upon compliance with the plan, and the larger herds have the biggest challenges for control.

PT1-039-002

Assessment of the effect of *Mycobacterium avium* subs. paratuberculosis in 305ME production and in udder health using HGLM, in Portuguese dairy cows.

Elisabete Martins ^{1 2 3,*}, Pedro Oliveira ¹, Bruno Oliveira ⁴, Denisa Mendonça ¹, Joao Niza-Ribeiro ^{1 2}¹Instituto de Ciências Biomédicas Abel Salazar, ²Instituto de Saúde Pública da Universidade do Porto (ISPUP), Oporto, ³Department of Veterinary Medicine, Escola Universitaria Vasco da Gama, Coimbra, ⁴Department of Computers Science, Faculdade de Ciências, Universidade do Porto, Oporto, Portugal

Objectives: To assess the impact on milk production and udder health of *Mycobacterium avium* subs. Paratuberculosis (MAP) infection in dairy cows in the Portuguese Dairy Control Program (PDCP), taking into account the intensity of infection at herd level.

Materials and Methods: All cows aged over 30 month's age, from 329 farms (in total 15,300 animals) were MAP tested by indirect biphasic ELISA. These cows represent 6.45% of the Portuguese dairy cow's population and 18.5% of cows (and 20% of farms) registered in PDCP. Cows were classified as positive (POS), negative (NEG), and dubious (DUB), based on (23,919 tests/20,221 cows) ELISA results. The farm intensity of infection was defined based on all individual ELISA results available to the farm in four levels: Strongly Negative (SNEG), Negative (NEG), Non-Negative (NNEG) and Positive (POS). Classification of each cow MAP status was performed taking into account its individual result within the farm intensity level in eight categories: NEG_SNEG, NEG cow in SNEG farm; NEG_NEG, negative cow in NEG farm; NEG_NNEG, NEG cow in NNEG farm; NEG_POS, NEG cow in POS farm; DUB_NNEG, DUB cow in NNEG farm; DUB_POS, DUB cow in POS farm; POS_NNEG, POS cow in NNEG farm; POS_POS, POS cow in POS herd. Records from 395,802 somatic cell counts (SCC) and Milk Productions (MP) of 40,065 lactations from 15,300 cows were available. Milk productions 305 day's equivalent (305MEP), average SCC and capability index for SCC (CpKccs) were calculated. Outcome variables: 305MEP and udder health were investigated using PTB status and PTB Level as explanatory variables, calving season as covariate, and farm and lactation number as hierarchical levels in Hierarchical Generalized Lineal Model (HGLM). Data was analyzed with IBM SPSS Statistics, version 23 and SuperMixe 2.1.

Results: Of the total 15,196 cows, 90.9% were NEG, 0.58% were DUB and 4.5% were POS. Correspondingly 4.67% of lactations were also positive. As to farms, 14.6% were S_NEG, 39.0% NEG, 18.2% N_NEG and 29.2% were POS. Positive and non-negative farms totalized 47.4% of observations. Only 17.2% of cows belonged to potentially MAP free farms; 58.3% of the cows were NEG animals in positive farms. The validity of 40,065 lactation records was assessed for NEG, DUB and POS cows, using qui-square test and no difference was found ($p=0.2$). Differences were found between the proportion of valid lactations by farm MAP status, by animal PTB level, and by farm PTB intensity level ($p<0.00$). Regardless of cow status, 62.2% of lactations and calving's, occurred in MAP-POS farms, suggesting high risk of contact with the agent. Only 18.1% of lactations/calvings occurred in MAP free farms. Overall, 305MEP lactation averages were higher in POS farms, than in SNEG, NEG and NNEG farms. Average 305MEP by cow status was higher in NEG than in POS cows for first, third and fourth lactations,

but higher in POS than in NEG for second, fifth, sixth, seventh and eighth lactations. As to PTB level, NEG_POS 305MEP were higher than POS_POS for second, third, fourth and fifth lactations Overall SCC were higher in POS farms than in the remainder, from first to third, sixth and seventh lactations; higher than SNEG and NNEG but lower than NEG for fourth and fifth lactations. Better understanding of these variations was achieved with HGLM.

Conclusions: This study indicates the existence of high prevalence of MAP infection in cows and farms and the potentially intense exposure of cows and calves to MAP infection since more than 60% of calvings and lactations occurred in infected farms. Bulk milk should also be exposed to contamination. The influence of MAP infection in udder health and milk production in Portuguese dairies is assessed.

Dysbiosis of the Fecal Microbiota in Cattle Infected with *Mycobacterium avium* subsp. paratuberculosis

Marie-Eve Fecteau ¹,*Dipti W. Pitta ¹Raymond W. Sweeney ¹

¹Clinical Studies-New Bolton Center, University of Pennsylvania, School of Veterinary Medicine, Kennett Square, United States

Objectives: The purpose of this study was to investigate the diversity patterns of fecal bacterial populations in cattle infected with *Mycobacterium avium* subsp. paratuberculosis (MAP), compared to those of uninfected control cattle, using phylogenomic analysis.

Materials and Methods: Fecal samples were selected from the New Bolton Center Johne's disease Laboratory's fecal repository to include samples from 20 naturally infected, non-clinical MAP-positive cows (positive group); 25 MAP-negative herd mates (exposed group); and 25 MAP-negative cows from a MAP-free herd (negative group).

Fecal samples were processed for genomic DNA extraction, using a commercially available DNA extraction kit. The extracted and purified DNA was amplified for the V1-V2 hyper-variable regions of the 16S rDNA gene using barcoded 8F and 357R primers. The amplicons were then bead purified using 1:1 Agentcourt AmPure XP beads. The purified products from the fecal samples were pooled in equal concentration prior to pyrosequencing. The 16S rDNA sequences obtained were decoded and analyzed using the QIIME pipeline.

Statistical analysis and graphical presentation of data was performed using R program. A non-parametric permutational multivariate ANOVA test, implemented in the vegan package for R, was conducted for each pair of bacterial communities, as measured by weighted UniFrac distance. To test for differences in taxon abundance, a generalized linear mixed model was constructed with the lme4 package for R. The model used a binomial link function and included a random effect term for each sample. The input data for the mixed model consisted of a two-column matrix containing (in column 1) the number of reads assigned to the taxon, and (in column 2) the number of reads assigned to other taxa.

Results: Approximately 2,52,380 reads were analyzed from 70 bacterial communities (average of 2,843 reads/sample). Clustering at 97% sequence similarity produced approximately 34,606 OTUs. Weighted and unweighted UniFrac distances by principal coordinate analysis showed a substantial effect ($P < 0.001$; Permanova test) of groups on the bacterial community composition. Taxonomic assignment of the OTUs identified 18 bacterial phyla across all samples. Bacteroidetes and Firmicutes constituted more than 95% of the bacterial population in the negative

and exposed groups. In the positive group, lineages of Actinobacteria and Proteobacteria increased and those of Bacteroidetes and Firmicutes decreased ($P < 0.001$). Actinobacteria was highly abundant (30% of the total bacteria) in the positive group compared to exposed and negative groups (0.1 – 0.2 %).

Conclusions: Fecal bacterial communities of MAP-positive cows varied significantly from those of cows from the exposed and negative groups. Bacterial communities within the exposed and negative groups were mostly homologous, whereas there was statistically significant greater variation between fecal samples in the MAP-positive cows. These findings are similar to the gastrointestinal dysbiosis demonstrated in patients suffering from various types of inflammatory bowel disease, including Crohn's disease (CD).

Comments: Background: Johne's disease (JD) is a chronic, intestinal infection of cattle, caused by *Mycobacterium avium* subsp. paratuberculosis (MAP). It results in granulomatous inflammation of the intestinal lining, leading to malabsorption, diarrhea, and weight loss. Crohn's disease (CD), a chronic, inflammatory gastrointestinal disease of humans, has many clinical and pathologic similarities to JD. Dysbiosis of the enteric microbiota has been demonstrated in CD patients. It is speculated that this dysbiosis may contribute to the intestinal inflammation observed in those patients.

PT1-039-004

The use of *Mycobacterium smegmatis* as a DNA extraction and RT-PCR internal control for the detection of MAP from a bovine faecal environment

Marcel De Kruijf ¹,*Aidan Coffey ¹Jim O'Mahony ¹

¹Biological Sciences, Cork Institute of Technology CIT, Cork, Ireland

Objectives: *Mycobacterium avium* subspecies paratuberculosis (MAP) inflicts large economic losses to the dairy industry worldwide. MAP DNA extraction from a bovine faecal environment has proven to be difficult, due to the resistant nature of the *Mycobacterium* cell wall. The aim of this study was to develop a novel specific MAP DNA extraction and realtime-(RT)-PCR internal control from a faecal environment. The use of *Mycobacterium smegmatis* mc2 155 strain with a molecular internal control (IC) facilitates the confirmation of MAP DNA and the IC by RT-PCR and therefore eliminates false negative results due to inefficient MAP cell lysis.

Materials and Methods: An 844 bp internal section of the ampicillin gene from the pUC19 vector was used for the development of the IC. IC primers were designed, which incorporated IS900 specific primers that would co-amplify both the IC and the MAP specific IS900 element all in one RT-PCR reaction with one primer set. The IC was cloned into the pMV261 vector by EcoRI and BamHI restriction enzymes and was transformed into the *M. smegmatis* mc2 155 strain. Samples with a combination of both MAP K10 and *M. smegmatis* IC DNA in different DNA concentrations were analyzed by RT-PCR and gel electrophoresis to assess the sensitivity of the IC. Similarly, MAP negative bovine faecal samples were artificially contaminated with a mixture of MAP K10 and *M. smegmatis* IC cells using different ratios of cell concentrations, followed by DNA extractions and RT-PCR analysis to assess the sensitivity of the IC in a bovine faecal environment.

Results: RT-PCR and agarose gel electrophoresis showed that the limit of detection was 4.00 10⁻⁶ ng/μl for both MAP K10 and *M. smegmatis* IC DNA. RT-PCR melting curve analysis yielded distinctive melting curve

peaks corresponding for both MAP K10 and *M. smegmatis* IC when the DNA concentration was 4.00 10⁻⁵ ng/μl, but no distinctive IC melting curve peaks were obtained at higher DNA concentrations than 4.00 10⁻⁵ ng/μl. When the DNA concentration was 10-fold higher for *M. smegmatis* IC compared to MAP K10 DNA, the limit of detection decreased from 4.00 10⁻⁶ ng/μl to 4.00 10⁻⁵ ng/μl for MAP K10. However, melting curve analysis yielded clear distinctive melting curve peaks for both MAP K10 and *M. smegmatis* IC. Similar results were obtained when faecal samples were spiked with a mixture of different ratios of cell concentrations of MAP K10 and *M. smegmatis* IC cells. The detection limit for MAP K10 cells combined with an equal amount of *M. smegmatis* IC cell dilution was as low as 102 CFU/ml for both cultures. Clear distinctive melting curve peaks were obtained for MAP IS900, whereas the melting curve peak obtained for IC was not seen until the cell dilution of 102 CFU/ml for both MAP K10 and *M. smegmatis* IC cells. Increasing the cell concentration of *M. smegmatis* IC cells 10-fold compared to MAP K10 cells resulted in more samples displaying two clear distinctive melting curve peaks corresponding to both IS900 and IC in the same RT-PCR reaction, but MAP sensitivity decreased from 102 to 103 CFU/ml.

Conclusions: By using the *M. smegmatis* strain mc2 155 as a novel internal control model for MAP DNA extractions, it has successfully proven that both MAP IS900 and the IC are successfully co-amplified by RT-PCR in a bovine faecal environment. These results show that the IC can be used to confirm successful DNA extraction and RT-PCR of MAP at low numbers in a faecal environment.

PT1-039-005

Comparative study investigating interference of SICCT on paratuberculosis ELISA in a herd pre- and post-removal of a clinical case.

Aideen E. Kennedy ^{1,*}, Jim O'Mahony ², Noel Byrne ³, Riona Sayers ¹

¹Animal & Biosciences, Teagasc, Moorepark, Fermoy, Co. Cork, ²Biological Sciences, Cork Institute of Technology, Cork, ³Animal & Biosciences, Teagasc, Moorepark, Fermoy, Co. Cork, Ireland

Objectives: *Mycobacterium avium* subspecies paratuberculosis (MAP) is the etiological agent of Johne's disease (JD), a chronic enteritis of ruminants. Administration of tuberculin as part of the single intradermal cervical comparative test (SICCT) for bovine tuberculosis (bTB) has been shown to interfere with MAP ELISA diagnostics. The aim of this study was to investigate the difference in interference of the SICCT test on MAP ELISA diagnostics in a herd pre- and post- removal of a clinical case.

Materials and Methods: A 139-cow dairy herd was recruited to the study. Monthly collection of blood samples for MAP ELISA testing began in May 2012 and continued to December 2014. This included collection of samples pre- (pre-SICCT) and post- (post-SICCT) administration of the compulsory annual SICCT herd test. Additional sampling runs (n=6) were completed up to 90 days post-SICCT in 2012 and 2014 to examine short-term variations in ELISA results. All samples were tested using the ID Screen Paratuberculosis Indirect ELISA (IDVet, France) with results reported as S/P%. Samples recording S/P% ratios of ≥70 S/P% were categorised as positive with all results below this cut-off categorised as negative.

In July 2013, this herd recorded a single cow displaying clinical signs of JD and the presence of the disease was confirmed on post-mortem. A further ten cows which recorded positive MAP ELISA results were culled from the herd and subsequently necropsied in winter 2013.

Multivariable generalised estimating equations (GEE) were used to investigate differences between pre- and post-SICCT S/P% in both 2012 and 2014. Independent variables included sampling time point (pre-SICCT, post-SICCT), parity, calving date, and breed. A Gaussian distribution and an identity link function with an exchangeable correlation was used for analyses. Variables recording P values <0.05 were considered significant. Means and standard errors were calculated for 2012 and 2014 pre- and post-SICCT data. A t-test was completed to investigate whether differences in S/P% between 2012 and 2014 were significant.

Results: All animals tested negative for bovine tuberculosis using SICCT in 2012 and 2014. Following removal of the single clinical JD case, no additional cow recorded pathological lesions indicative of JD. Results from 2012 are outlined in detail in Kennedy et al., 2014. In brief, a pre-SICCT prevalence of 8% increased to 39% post-SICCT, with prevalence returning to pre-SICCT levels by day 71 following administration of tuberculin. In 2014, all cows tested MAP ELISA negative pre-SICCT and had tested negative for four months prior to tuberculin administration, following the culling programme. The proportion of ELISA positives post-SICCT increased to 30%, almost 10% lower than 2012. By day 57 post-SICCT, GEE analysis highlighted no statistical difference between pre- and post-SICCT ELISA readings (P=0.01). It should be noted, however, although S/P% ratios were not statistically different, four cows had S/P% values above the positive cut-off (range 76.7 to 114.5). Only by day 91, did all animals test ELISA negative. Mean S/P% and standard errors from 2012 and 2014 are outlined in the table below and highlights that S/P% are significantly lower in 2014.

	2012	2014	t-test
	Mean S/P% (SE)	Mean S/P% (SE)	P value
Pre-SICCT	26.27 (3.04)	11.46 (0.08)	<0.001
Post-SICCT	44.87 (2.30)	32.43 (1.70)	<0.001

Conclusions: Testing for bovine tuberculosis using the SICCT interferes with MAP ELISA diagnostics in both seronegative and seropositive herds. From the results of the current study, it would appear prudent to avoid MAP ELISA testing of a seronegative herd for a minimum of three months post-SICCT. The overall reduction in S/P% between 2012 and 2014 may reflect the contribution of a MAP positive individual to the anamnestic response in herd mates.

Long term experimental infection of cattle with *Mycobacterium avium* subspecies paratuberculosis (MAP): the first 2 years

Louise Britton ^{1,*}, Colm Brady ², Joseph Cassidy ¹, Jim O'Donovan ³, Nola Leonard ¹, Eamon Gormley ¹, Ronan Shaughnessy ¹, Stephen V. Gordon ¹, Bryan Markey ¹

¹School of Veterinary Medicine, University College Dublin, Dublin, ²Department of Agriculture, Food and the Marine, Central Veterinary Research Laboratory, Kildare, ³Department of Agriculture, Food and the Marine, Regional Veterinary Laboratory, Cork, Ireland

Objectives: *Mycobacterium avium* subspecies paratuberculosis (MAP) causes Johne's disease, a chronic wasting disease of domestic ruminants. The disease has a long subclinical phase before the onset of clinical signs. Currently, it remains challenging to identify the MAP status of subclinically infected cattle. A long term bovine experimental infection study has commenced as part of the IconMAP project, funded by the Irish Department of Agriculture, Food and the Marine (DAFM). Its aim is to search for novel biomarkers of infection status and create a biobank of tissue and blood samples for test evaluation and validation.

Materials and Methods: The experimental infection has been conducted in accordance with the Irish Health Products Regulatory Authority (HPRA) and University College Dublin (UCD) Animal Research Ethics Approval Committee (AREC) requirements. Two low risk farms were identified to source male calves; the calves in the infected group (n=35) received 3.8X10⁹ CFU MAP twice orally at approximately 4 weeks of age, whereas the control calves (n=20) received a placebo. Their MAP infection status is being monitored using currently available diagnostic tests. The IFN- γ assay (Bovigam®) was used to assess the cell mediated immune response against MAP infection. Faecal and tissue samples were cultured for MAP (TREK ESP® para-JEM® system), while the humoral immune response has been evaluated using a commercial ELISA (Idexx). At the month 12 post-infection interval, thirteen animals (n=8 infected; 5 controls) were euthanized for detailed post-mortem examination.

Results: IFN- γ assay (Bovigam®) results are available for months 2, 3, 6, 10, 12, 16, 20 and 24 post-infection and indicate that the experimental infection was successful. Faecal samples from the pre-infection time-point and months 3, 6, 9, 12, 16 and 20 post-infection have been cultured and are negative. Serological results are available from the pre-infection time-point and months 3, 6, 10, 12, 16, 20 and 24 post-infection; a single animal tested positive at the month 10 post-infection interval, two animals tested positive at the month 16 post-infection interval, six animals tested positive at the month 20 post-infection interval and four animals tested positive at the month 24 post-infection interval. At the month 12 post-infection interval, only minor pathological differences were seen between the groups and ileal tissue samples were MAP culture negative.

Conclusions: These results clearly demonstrate the difficulties of identifying subclinically infected cattle using conventional diagnostic tests and emphasize the requirement for novel diagnostic biomarkers of infection status.

PT2-040-001

Transmission of *Mycobacterium Avium* Spp Paratuberculosis; The Role of Fecal Shedding in Dairy Calves

Caroline Corbett¹ Herman Barkema¹ Jeroen D. Buck¹ Rienske Mortier² Robert Wolf³ Karin Orsel^{1,*}

¹Production Animal Health, University of Calgary/Veterinary Medicine, ²Dekens Veterinary Services, Calgary, Canada, ³Fachabteilung Gesundheit und Pflegemanagement, Amt der Steiermarkischen Landesregierung, Graz, Austria

Objectives: In Johne's disease control, it is generally assumed that calves rarely shed MAP bacteria and that calf-to-calf transmission is of minor importance. Throughout an experimental trial, 61% of the inoculated calves, representing different age and dose groups, shed MAP in the feces at least once. Additionally, we performed a field study on MAP-positive dairy farms and found 2% of young stock MAP culture-

positive with fecal shedding confirmed in all age groups up to 2 years of age. The objective of our follow-up experimental transmission study was to determine if transmission to susceptible penmates occurs.

Materials and Methods: For this study, 32 newborn Holstein-Friesian bull calves were allocated into 8 pens of 4 calves. In 7 of these pens, 2 calves were inoculated with MAP, and 2 calves acted as the contact exposed. The 8th pen was designated as a control group. After initial separation to prevent infections to occur from passive shedding of the oral MAP challenge, the calves were group-housed for 3 months to allow for any potential transmission to occur. After 3 months of group housing, the contact exposed calves were individually housed for another 3 months to allow establishment of infection, whereas the inoculated calves were euthanized. Blood samples for antibody and interferon- γ detection were collected weekly, fecal samples for evidence of MAP shedding were collected three times a week for all animals. Environmental samples of the pens were collected weekly. At the end of the trial all calves were submitted for necropsy to confirm infection in the tissues. The laboratory results will be used to define R0 as well as the transmission parameter β .

Results: Fecal shedding was observed by bacterial culture in all inoculated calves. Although serology and interferon- γ results are still pending, fecal shedding has been confirmed in all contact exposed calves. During the first 3 months of the group housing, between 2 and 10 fecal samples of the contact exposed calves tested positive. Several tissues collected at necropsy of inoculated calves were culture-positive indicating infection from inoculation. The tissue results from the contact-exposed calves are pending.

Conclusions: Based on fecal shedding of MAP, in all 7 MAP challenge groups, transmission seemed to have occurred to contact exposed penmates; pending tissue culture confirmation. This study underlines the importance of calf-to-calf transmission of MAP resulting in infection. JD control programs should implement control measures focused on this route of transmission to achieve a reduction in within-herd prevalence on dairy farms.

PT2-040-002

The diagnostic performance of an antibody ELISA using colostrum to determine the disease status of a Victorian Jersey dairy herd infected with MAP.

Peter Cockcroft ^{1,*} Caitlin J. Jenvey ¹ Michael P. Reichel ²

¹School of Animal and Veterinary Sciences, University of Adelaide, Adelaide, Australia, ²School of Veterinary Medicine, City University of Hong Kong, Hong Kong, Hong Kong

Objectives: Colostrum samples may improve the diagnostic accuracy of some tests when compared to serum for some cattle diseases due to the high concentrations of immunoglobulins present within this sample type. The enzyme-linked immunosorbent assay (ELISA) for Johne's disease is one such test, as it suffers from low sensitivity when testing serum samples collected during the subclinical stage of infection. The aim of the study was to compare the diagnostic performance of a *Mycobacterium avium* subspecies paratuberculosis (MAP) antibody enzyme linked immunosorbent assay with serum or colostrum and using faecal culture as a reference standard.

Materials and Methods: Blood and colostrum samples were collected from 34 Jersey dairy cows from a dairy farm in the State of Victoria, Australia which had previously been confirmed as infected with MAP. The samples were tested for antibodies against MAP by ELISA. Faecal

samples were also collected and tested using a high throughput-Johne's polymerase chain reaction (HT-J PCR) and faecal culture (FC), which was used as the reference test. The diagnostic accuracy (DA) and area under the curve (AUC) were calculated. The HT-J PCR and faecal culture results were also compared.

Results: Of the 34 cows in this study, 4 had FC results consistent with MAP infection. The HT-J PCR did not identify any FC positive cows. Using a 1:20 dilution and S/P ratio cut-off threshold of 0.15, both serum (DA 0.88; AUC 0.44) and colostrum (DA 0.85; AUC 0.37) were unable to identify any of the FC positive cows. With a decrease in sample dilution, serum was still unable to identify any FC positive cows, but colostrum was able to identify 3/4 FC positive cows at a dilution of 1:5 and S/P ratio cut-off threshold of 0.15. The resulting DA and AUC values for colostrum were 0.88 and 0.73, respectively.

Conclusions: In this study, using faecal culture as a reference standard, the diagnostic performance of aMAP antibody ELISA using colostrum was superior to that using serum as well as the HT-J PCR to determine the disease status of a Victorian Jersey dairy herd infected with Johne's disease. Colostrum may provide improved identification of animals in the early stages of infection with MAP. This sample type is easy for farmers to collect and store and the test is relatively inexpensive.

PT2-040-003

Diagnosis of sub-clinical infection with *Mycobacterium avium* subsp. *paratuberculosis* and its effect on milk production

Andrew Bates ¹, *Rory O'Brien ² Simon Liggett ² Frank Griffin ²

¹Centre for Dairy Excellence, Vetlife, New Zealand, Geraldine, ²Disease Research Laboratory, Dept. of Microbiology & Immunology, University of Otago, Dunedin, New Zealand

Objectives: A pilot project to determine if a novel diagnostic strategy coupling multi-antigen serological assay with faecal sampling for enumeration of *Mycobacterium avium* subsp. *paratuberculosis* (MAP) shedding in faeces by quantitative PCR could be used within a commercial 1200 cow dairy herd in South Canterbury, New Zealand to identify and cull animals infected with MAP before clinical disease was evident. Secondary aims were to estimate the association between MAP status as defined by serological and faecal PCR (fPCR) and milk production.

Materials and Methods: In the autumn of 2014 and 2015, a plain coccygeal blood sample was collected from all milking cows in the enrolled herd. The Disease Research Laboratory (DRL), University of Otago, assayed samples for circulating antibody to MAP using two ELISA tests, ParalisaTM and IDEXX. The ParalisaTM test quantifies antibody responses to two distinct protein antigens in parallel, Johnin (PPD-J) and a Protoplasmic Antigen (PPA). An additional MAP-specific recombinant protein antigen, Ag1Del1, was incorporated into the ParalisaTM test and the three tests were read in parallel alongside the IDEXX ELISA assay. For all four serological antigens a classification of Not Detected was returned for results of <50 ELISA Units (EU), readings of 50-100 EU in any one test were low, readings of 101-150 EU as moderate, and readings of >150 EU as high.

Seven days later, a faecal sample (10g approx.) was collected from each cow testing low, moderate or high to any of the ELISA tests and forwarded to DRL for enumeration of MAP shedding in faeces by quantitative fPCR. Faecal sample data were stratified into shedding categories with MAP shedding scores of <103 genomes/ml faeces classified as Not Detected,

scores ≥103-<104 genomes/ml as Moderate and counts ≥104 genomes/ml as High.

The outcome variable was milk solids production (kg milk solids per cow per season). Predictor variables were days in milk, age at sampling in years, ELISA test status and fPCR status. A mixed model with a random intercept for cow and a fixed effect interaction term for year-ELISA gave the model with the lowest Likelihood.

Results: The prevalence of ELISA positive cows was 297/1122 (26.5%, 95%CI=23.9-29.1%) in 2013-14 and 108/1069 (10.2%, 95%CI=8.4-12.0%) in 2014-15 (p<0.001). The prevalence of fPCR positive cows amongst these ELISA positive cows was 55/297 (18.5%, 95%CI=13.9-23.2%) in 2013-14 and 27/108 (25%, 95%CI=16.5-33.0) in 2014-15, (p=0.177).

Milk production was significantly greater in 2014-15 (473kgMS/cow 95%CI=466-479) than 2013-14 (430kgMS/cow (95%CI=424-435), p<0.001). Positive ELISA and faecal PCR were both significant in the final mixed model but there was a significant interaction between year and ELISA status such that the effect of ELISA status was greater in 2013-14 than 2014-15. Across both years the marginal mean production for cows with a high ELISA status was predicted to be 65kgMS/cow less and cows with a low or moderate ELISA status 39kgMS/cow less than cows with a non-detected ELISA status (p<0.001). Cows with a faecal PCR ≥103 genomes/ml faeces produced 46kgMS/year less (p<0.001) than cows with a faecal PCR count <103.

Of the 297 ELISA positive cows in 2013-14, for 2014-15, 122 were culled, 61 were still positive and 114 were ELISA negative. Of the 55 cows testing positive for fPCR in 2013-14, for 2014-15, 52 were culled and 3 were still fPCR positive.

At the observed prevalence of fPCR in this herd, estimation of the sensitivity and specificity of the ELISA test for fPCR status suggest that the ELISA test is very useful for identifying animals that will have an fPCR <103 genomes/ml faeces with a negative predictive value = 92.6% (95%CI=87.2-97.9%).

Conclusions: In the absence of other clinical signs, herd screening using a combined ELISA test for MAP allowed identification of animals with a significantly decreased milk production. ELISA negative animals had a high probability of not being faecal shedders.

PT2-040-004

Experiences with developing a commercial solution to Johne's control in the UK

Peter Orpin^{1,2}, *Richard J. Sibley³

¹Park Vet Group, Leicester, ²Special Lecturer, Nottingham University, Nottingham, United Kingdom, ³Westridge Veterinary Group, Witheridge, Tiverton, United Kingdom

Objectives: The control of Johnes Disease (JD) or paratuberculosis in dairy herds is always problematic. The disease has a long incubation with losses occurring in the pre-clinical phase or indirectly as a consequence of increased culling. Effective control depends on education, a clear understanding of the potential economic effects and the enthusiasm of the farmer to implement the changes required to reduce the risk of spread of disease within the herd. In the UK we have sought to find commercial solutions to deliver a National Johnes Management Plan (NJMP) to drive engagement amongst the farmers, vets and wider industry.

Materials and Methods: In 2010 Dairy UK (milk processor representative body) formed a Johnes Action Group to tackle JD in the UK dairy sector.

A collaborative JD engagement programme was developed to engage dairy farmers, milk processors, regional monitoring organisations and veterinary surgeons with the effective control of Johne's disease. The early outputs of the group were focused on establishing coherent messages for inclusion in vet and farmer training, standardised surveillance (targeted 30 cow screen) combined with a commitment to robust risk assessment and management of JD. As a parallel development a commercial web based health planning tool (www.myhealthyherd.com) was designed linking the farmers, vets, monitoring organisations and labs. A specific Infectious Disease manager module within the program facilitated structured risk assessments of disease entry and spread to be completed. A prevalence prediction graph was created using a combination of a targeted milk ELISA sampling of 30 high risk cows and risk assessment results to prompt action from the farmers. The myhealthyherd tool was used to underpin two large regional funded Johnes program and a processor driven education program (Operation Johnes)

In 2015 the engagement plan was enhanced by the development of the National Johnes Management Plan which seeks to engage the processors to encourage their farmers to commit to effective JD control. The first phase of this programme focuses on farmers committing to testing for JD, reviewing their risks and choosing one of 6 control strategies for their farm.

Results: The first 5 years of the programme was viewed as a national "JD engagement" process with the emphasis on education of vets and farmers with 3 main strands of activity; private vets, funded regional schemes and a processor supported farmer engagement scheme (Operation Johnes). Over 2200 farmers completed risk assessments using myhealthyherd.

In the last 5 years over 300 farmer meetings to 2500+ farmers have been delivered with the support of their milk processors with a further unknown number delivered by private vets. Over 350 vets have been educated in the principles of JD control. The farmers and vets were then encouraged to work together to develop an effective JD management plan for their herds using the resources made available.

6 control strategies were developed and accepted within the Johnes Action Group and this has allowed a commercially acceptable solution to be adopted by farmers. The most popular strategies involved improved farm management and testing (50%), improved farm management alone (26%), test and cull (11%) and biosecurity protect and monitor (9%). Vaccination and breed to terminal sire were chosen by less than 2% of farmers. Over 2000 herds now test their herd quarterly for JD.

By September 2016 NJMP has progressed through further financial support from milk processors whereupon 77% of the GB milk supply will be asked to confirm they have tested for presence and assessed the risks of JD within their herds and chosen a suitable control strategy. A webinar 4 stage module of vet training is planned for 2015/16 to create a list of approved JD vets.

Conclusions: Globally well managed voluntary JD programs appears to engage up to 35% of dairy herds. The UK is on target to achieve this level of engagement. The challenge remains as to how well the remaining herds (often of lower prevalence and aspiration) can be successfully engaged with the absence of commercial drivers or compulsion. There is no evidence of a premium to justify risk based trading with many farmers preferring to breed their own replacements. Many challenges remain but with minimal funding and a coherent effort progress can be made to reduce the prevalence of JD within a region or country using commercial approaches.

PT2-040-005

The Thuringian bovine Johne's disease control program – results, experiences and conclusions for the future control strategy

Karsten Donat ^{1,*}

¹Animal Health Service, Thüringer Tierseuchenkasse (Thuringian Animal Diseases Fund), Jena, Germany

Objectives: Control of Johne's disease is being discussed controversially, and the eradication of the infectious agent at herd level is disbelieved. Furthermore, prospects to keep herds free from *Mycobacterium avium* ssp. *paratuberculosis* (MAP) or MAP-free and the sustainability of the control efforts are questioned. This study aimed at evaluating the results achieved in voluntary paratuberculosis control measures in cattle herds in Thuringia, federal state of Germany, between 2008 and 2014, and at drawing conclusions for further practice.

Materials and Methods: A total of 76 dairy herds and 29 cow-calf beef herds, keeping a total of 33,614 cattle older than 24 months, enrolled in the voluntary control program and were included into the analysis. MAP shedders were detected by annual testing of cattle older than 24 months by individual faecal culture for *Mycobacterium avium* ssp. *paratuberculosis* (MAP). Only herds with more than 50% of those cattle tested each year were considered. Cumulative incidence (CI) was used to monitor the control progress. A herd was classified as MAP-positive if at least one MAP shedder was detected within the herd and remained MAP-positive until it successfully passed the three-year certification procedure. Herds without any detection of MAP during three consecutive years were certified as MAP-free. Fisher's exact test was used to analyse frequencies of MAP-positive and MAP-free herds relating to their initial MAP status, and a stratified analysis with respect to farm type (dairy or beef) was performed using the Mantel Haenszel test procedure. To analyse the progress of control in dairy herds, a subset of 25 MAP-positive herds was selected. Reduction of CI over the years was analysed using a one-way ANOVA for repeated measurements, and, with respect to the initial cumulative incidence in 2008, using a two-way ANOVA.

Results: In 2014, 27 dairy herds and 13 beef cow-calf herds had been certified as being MAP-free and in seven dairy and six beef herds no MAP shedder was detected and the beginning of the certification period was marked. In three initially MAP-negative herds a reintroduction of the infectious agent was detected during the control period, two of which have been re-certified again. Compared to the MAP-positive herds, MAP-negative herds had a higher chance (odds ratio 32.9; $p < 0.0001$) of achieving a certification as a MAP-free herd until 2014. In 13 of 67 MAP-positive herds (19.4%) the infectious agent was eradicated and the herds got certified as MAP-free. Herds' CI decreased significantly from 2008 ($14.0 \pm 3.6\%$) to 2014 ($5.6\% \pm 1.3\%$) in the subset of 25 MAP-positive dairy herds. Regarding the initial situation in 2008 (CI < 5% or CI > 5%) the control progress differed significantly in a two-way ANOVA.

Conclusions: The results demonstrate that the eradication of paratuberculosis is feasible on herd level. A herd monitoring based on faecal culture tests and a certification period of three years is adequate to justify the status "MAP-free", even if the herd had been MAP-positive in the past. The status "MAP-free" can be maintained by implementing biosecurity and trade controls. Once a herd has achieved a low CI level, lowering the number of new cases per year gets increasingly difficult. Control efforts should be intensified in these herds, e. g. by implementing more strict hygienic measures and by culling the MAP shedders in short term.

PH-028-001

Perception of bovine ringworm by German practicing veterinarians

Joachim L. Kleen^{1,*}, Ulrike Exner², Tatjana Andres², Regina Strie²¹CowConsult, Uplengen, ²Boehringer Ingelheim Vetmedica, Ingelheim, Germany

Objectives: Bovine ringworm (tinea) is generally being described as a disease regularly occurring in cattle. Actual data are, however, scarce and frequently anecdotal in character. Despite its zoonotic potential, the disease is not being officially controlled in most countries and little is known on the perception of the disease in vets, public or farmers. It was objective of this study to assess the awareness of ringworm by practicing vets and how they judge the perception of the disease by clients.

Materials and Methods: A questionnaire was developed to investigate the perception of practicing veterinarians on ringworm. The areas covered were general assessment of the disease and its zoonotic potential, the perception by farmers, characteristics of the disease and measures against it. The questionnaire was issued to 378 participants before a course in continuing education for practicing veterinarians dealing with the topic of bovine ringworm on 10 occasions. A statement on ringworm could be scored between 1 (no agreement) and 10 (complete agreement). Results were statistically described, an average score was calculated for each question using the formula: (Score*number of participants for this score)/Sum of all scores/Number of participants.

Results: The majority of the participants agreed that ringworm was a serious animal health problem (Agreement score of 7.6) while they generally were neutral about its zoonotic potential being appreciated adequately (Score 5.1). Most participants stated that they diagnosed ringworm on farms regularly (Score 7.3) and that they were actively involved in treating or eradicating the disease (Score 6.8). The participating veterinarians were neutral on the perception of ringworm as animal health problem by the farms themselves as this statement received a score of 5.7. A similar score was calculated on the statement that farms would be actively asking for advice or treatment (5.6). A majority of participants felt that vaccination was helpful and to be recommended (Agreement score of 8.4). The participants were neutral on the statement that the topic had motivated them to visit the course where the survey was done (Score 5.3).

Conclusions: Practising veterinarians feel that bovine ringworm is being perceived less important by farmers than by themselves. Veterinarians judge that the zoonotic potential is underestimated. While vets seem to encounter the disease regularly they apparently are not active in treating or preventing the disease as much. It is to be concluded that more information and offers on the treatment of ringworm by veterinarians could contribute to engaging in the disease more effectively.

Objectives: For animal disease surveillance, in targeted sampling specific herds or animals are selected for sampling due to specific features. For the control of Bovine viral diarrhoea (BVD), testing of a group of young stock is a common method. However, on-farm sampling of young stock is often labour-intensive and dangerous. Therefore, taking samples at the slaughterhouse during meat inspection is straight forward, given that animals to be sampled can be easily identified. We present an application to inform the meat inspectors by highlighting animals to be sampled. They assess the application online through the slaughterhouse ERP-system.

Materials and Methods: We developed a Web-based application (RiBeS) that includes an interface between the animal movement database and the abattoirs' ERP-systems. In RiBeS it is possible to define different types of surveillance an early-detection programmes for various diseases or other targets. As in Switzerland blood sampling was previously not done at meat inspection, we conducted a pilot study at four large Swiss abattoirs and tested various sampling schemes. In May 2015 we used RiBeS to take samples for bluetongue surveillance. Since the pilot study in February we developed the application further and will start with large scale sampling for BVD surveillance in February 2016 at the seven largest abattoirs. With these seven abattoirs, we reach about 80% of the cattle slaughtered. However, there are several hundreds of small abattoirs. For a nationwide coverage, these abattoirs are also important. We plan to test the online application in 2016 for the meat inspectors at these abattoirs.

Results: In the pilot study we were able to confirm that taking samples at the abattoir is more effective than sampling on-farm. However, the investigation costs need to be considered and must be balanced against the savings. Obviously, large numbers of samples lead to a faster return of investment. In the pilot study it was possible to take samples from almost all highlighted animals. Blood samples were taken either from heart at inspection of organs or from the carcass (Plexus brachialis). For high frequent sampling, the organisation at meat inspection needs to be modified and additional personal is necessary. In the pilot study and for bluetongue surveillance we took about 4'500 samples. For the bluetongue samples, the rate of non-eligible samples was much lower with RiBeS than in the previous year without, being 0.1% compared to 0.7%.

Conclusions: Targeted sampling at the abattoirs is feasible and economical. However, the investigation costs are high and need to be well balance against the savings. To sample for animal health programmes at the abattoir might be an important function for meat inspectors given the reduction of classical tasks in meat inspection.

A systematic review and meta-analysis of control methods for non-typhoidal Salmonella pre-harvest in cattle

Barbara Wilhelm^{1,*}, Ian Young², Sarah Cahill³, Rei Nakagawa⁴, Patricia Desmarchalier⁵, Andrijana Rajic⁶

¹University of Guelph, Vermilion, AB, ²School of Occupational and Public Health, Ryerson University, Toronto, Canada, ³Food Safety and Quality Unit, Food and Agriculture Organization of the United Nations,, Rome, Italy, ⁴Department of Food Safety and Zoonoses, World Health Organization, Geneva, Switzerland, ⁵Food Safety Principles, Pullenvale, Australia, ⁶Population Medicine, University of Guelph, Guelph, Canada

Objectives: A systematic review of the effectiveness of interventions to reduce non-typhoidal Salmonella spp. (hereafter referred to as

PH-028-002

RiBeS – an application for targeted sampling of cattle during meat inspection at Swiss abattoirs for animal health surveillance programmes

Heinzpeter Schwermer^{1,*}, Jürg Danuser¹, Sara Schärer¹, Gaby Freudiger², Josef Schmidt¹¹Animal Health, Federal Food Safety and Veterinary Office FSVO, 3003 Berne, ²Identitas AG, 3018 Berne, Switzerland

Salmonella) prevalence or concentration in beef and pork was undertaken to provide support to risk managers. This work reports the systematic review findings pertaining to pre-harvest cattle.

Materials and Methods: A broad search was conducted in 2 electronic databases, with additional search verification and grey literature searches conducted. Level 1 relevance screening excluded irrelevant citations; level 2 confirmed relevance and categorized studies. At level 3 screening, data were extracted, and intervention categories (non-therapeutic antimicrobials, biosecurity, feed management strategies, probiotics, and vaccination) were descriptively summarized. Meta-analysis (MA) was performed where 2 or more studies investigated the same intervention in comparable populations. The Risk Ratio (RR) was deemed the preferred summary measure of effect where data supported its computation. We used the Grading of Recommendation, Assessment, Development and Evaluation (GRADE) approach endorsed by the Cochrane Collaboration to assess the weight of evidence for each data subgroup.

Results: Seventy-one relevant primary research studies and four risk assessments/stochastic models were captured. Maintenance of a closed herd was significantly associated with reduced odds of Salmonella on-farm in 7 observational studies. Inconsistent effects of hygiene measures were reported across 3 observational studies. Feeding monensin had a non-significant treatment effect on Salmonella shedding in 3 controlled trials (CTs) with 'Moderate' GRADE rating. Three observational studies reported a significantly ($P < 0.05$) protective effect of feeding antimicrobial-supplemented milk replacer on dairy calf fecal Salmonella shedding. Inconsistent findings were reported for feeding distilled brewers' grains ($n = 3$ CTs, 4 observational studies), cottonseed hulls ($n = 3$ observational studies), or feed withdrawal prior to slaughter ($n = 1$ quasi-experiment, 1 observational study). Feeding of probiotics yielded a non-significant MA treatment effect across 2 CTs with a 'Low' GRADE rating. Salmonella vaccines in cattle had inconsistent treatment effects on fecal shedding, and modest magnitude of summary estimate of effect (Median RR = 0.96, 95% CI (0.75, 1.11)) with 'Very low' GRADE rating across 7 CTs. Heterogeneity of treatment effect in the vaccination dataset could reflect differences between bacterins and live vaccines, or possible mis-matches between vaccine and circulating serovars of Salmonella in the study populations.

Conclusions: While each intervention category was reported effective in some settings, biosecurity practises were most consistently effective. Use of GRADE to assess weight of evidence was found helpful in describing the level of confidence in the magnitude of MA summary estimates.

PH-028-004

The prevalence of verocytotoxigenic *E. coli* O157 (VTEC O157) in British cattle populations

Madeleine K. Henry^{1,*}, Sue C. Tongue¹, Judith Evans¹, Catriona Webster¹, Alice Willett², Margo E. Chase-Topping³, David Gally⁴, George J. Gunn¹

¹Epidemiology Research Unit, SRUC, Inverness, ²Sustainable Food and Farming, ADAS UK Ltd., Wolverhampton, ³Centre for Immunity, Infection and Evolution, ⁴The Roslin Institute, University of Edinburgh, Edinburgh, United Kingdom

Objectives: One of the objectives of the British *E. coli* O157 in Cattle Survey (BECS) is to generate new estimates for the prevalence of VTEC O157 in cattle destined for slaughter in both Scotland and in England & Wales, during September 2014 to November 2015. These estimates will build on previous cross-sectional surveys conducted in Scotland

and provide the first equivalent national estimate for England & Wales. These estimates are important as human clinical infection with VTEC O157 has been strongly associated with exposure to livestock faeces and previous sequencing work has demonstrated that Scottish cattle and human cases are closely related.

Materials and Methods: Cross-sectional surveys of 160 farms in England and Wales and 110 farms have just been completed (November 2015). In Scotland, the 110 farms are a random sample of those farms previously visited in two Scottish cross sectional surveys (1998/2000 SEERAD and 2002/2004 IPRAVE), while in England and Wales the design is a randomised, structured survey that replicates the original Scottish surveys. Faecal pat samples have been taken to determine the VTEC O157 status of the farm, according to the previous survey protocols i.e. the cattle preferentially sampled have been weaned animals ultimately destined to enter the food chain; 1g of faeces from each pat was tested for VTEC O157 using IMS; and one isolate per positive faecal sample was tested for Vero toxin 1 and 2, using multiplex PCR. The isolates will subsequently be phage-typed and a temporal and spatially appropriate subset will be whole genome sequenced.

Results: The data from these surveys will be used to generate new herd-level and pat-level prevalence estimates for VTEC O157 in cattle, in each of the populations – Scotland and England & Wales – using generalised linear mixed models. In Scotland, these values will be compared to previous estimates generated using similar methodology. The estimates will also enable comparisons between the two populations. Crude preliminary estimates suggest similar herd-level prevalence for Scotland but a difference between Scotland and England & Wales. Questionnaire data collected at the time of sampling will also be analysed as a means of explaining any differences observed.

Conclusions: Cattle are a recognised reservoir for human clinical VTEC O157 infection. Establishing current baseline prevalence estimates in cattle is a vital first step in any investigation of whether cattle shedding can be linked firstly to the observed consistently high rate of sporadic clinical infection of humans with VTEC O157 in Scotland, and secondly to the observed difference in the human clinical infection rate between Scotland and England & Wales. Future analyses of isolates obtained from these surveys will include the current strain composition and comparisons with data from human clinical cases in the same time period (FS101055).

PH-028-005

Farmers' knowledge of the risk of spread of infection from animals to humans and their transmission prevention practices carried out in 2015.

Maresa Sheehan^{1,*}, Marrita Mahon², Pat Kelleher³, Alan Johnson⁴, Sarah Doyle⁵

¹Department of Agriculture, Food and the Marine, Kilkenny Regional Veterinary Laboratory, ²Public Health Department, H.S.E., H.S.E., ³Department of Agriculture, Food and the Marine, Department of Agriculture, Kilkenny, ⁴Department of Agriculture, Food and the Marine, Limerick, ⁵Public Health Department, HSE, H.S.E., Kilkenny, Ireland

Objectives: To determine farmers' knowledge of zoonoses and of the risk of infection posed to humans by some common animal exposures. To determine whether (and how often) farmers carry out simple infection prevention activities on their farms. To find out where farmers get information on animal disease, to inform future health promotion activities.

Materials and Methods: This was a survey of people who submitted material to the Department of Agriculture Food and the Marine's (DAFM) Regional Veterinary Laboratories (RVLs) between February and July 2015. Consecutive persons who presented to the RVLs to submit material for examination during the time period of the study were asked by reception staff to complete the survey. A record was kept of the number of people who declined the survey. The questionnaire was designed by veterinary, scientific and medical members of the South East Regional Zoonoses Committee. Questions related to the farmers' knowledge of zoonoses, their knowledge of the transmission modes/risks from animals to humans, consumption of unpasteurised milk, the water source on the farm house and the testing carried out if this water source was a private well. Other questions were designed to investigate the personal protective equipment worn and other measures undertaken, such as hand washing, to reduce the risk of disease transmission. Demographics of the farmers in the survey were gathered as well as ascertaining how they source information regarding zoonoses.

Results: 1044 farmers completed the survey, 198 refused. Of responding dairy farmers, 39% drink unpasteurised milk once a week or more frequently. 90.1% of the dairy farmers who frequently drink unpasteurised milk didn't know or did not answer the question "Might you or a family member get an infection from healthy animals?". Of responding farmers, 58.5% had private well water at home. Only 35.8% of owners of private wells got their water tested yearly, 43.4% of those with private wells got their water tested less frequently than once a year and 18.3% of private well owners have never got their water tested. Over half of farmers, 52.2%, were not aware of the risk of children contracting vomiting and diarrhoea from animals. Slightly over half (50.6% and 52.3%, respectively), were not aware that disease could be contracted from sick poultry or pets. A high percentage of farmers who completed the survey (89.9%) were not aware that infection can be got from apparently healthy animals. The knowledge of the risk to pregnant women of infection from aborting animals and around animals giving birth was high, with 88.4% of farmers being aware that it was unsafe for pregnant women to be in the vicinity of animals giving birth. The most frequently accessed source of information regarding diseases on farms were: veterinarians (n=913), newspapers (n=519), Teagasc (n=501), DAFM (n=385), social media (n=153), agricultural shows (n=130) and medical practitioners (n=57). Most farmers indicated they used more than one source of information.

Conclusions: The survey findings indicate that the level of farmers' knowledge and awareness about the spread of disease from animals to humans is concerning. Further, this survey has identified the need for further education of the farming community to increase awareness of both the potential biohazards present on farms and the practical measures that can be taken to mitigate the risk of zoonosis.

RE1-023-001

Housing condition (indoor versus outdoor) does not affect the performance of activity meters for oestrus detection in dairy cattle

Judith Roelofs ^{1,*}, Elaine van Erp-van der Kooij ²

¹Animal Husbandry & Animal Care, ²Applied Biology, HAS University of Applied Sciences, 's-Hertogenbosch, Netherlands

Objectives: Pedometers and neck mounted activity tags are widely used for oestrus detection. These tags give oestrus alerts when the activity of a cow exceeds a threshold. To perform well, a daily routine in activity patterns could be important. In the Netherlands, dairy cows are housed outdoors from spring until autumn for 6 to 9 hours a day, depending on the weather. This could mean that in this period the routine is disturbed. The objectives of this study were to investigate whether performance of activity tags differed 1) between pedometers and neck mounted activity collars and 2) between housing conditions (partly outdoor or indoors).

Materials and Methods: Two dairy farms with Holstein-Friesian cows were used in the study. Cows were equipped with pedometers (STL) and neck mounted activity collars (STN) (Smarttag Leg and Smarttag Neck, Nedap Livestock Management, the Netherlands). The study started in the autumn, when the cows were housed partly outdoors ('pasture', September - November) and continued during winter, when the cows were kept indoors day and night ('indoors', November - January). Starting from 20 days after calving milk samples for progesterone analyses were taken two times weekly during morning milking. Progesterone concentration was measured using a commercial ELISA kit (Ridgeway Science, Gloucester, UK). Every oestrus alert generated by the activity tags was compared with the progesterone profile. When an activity alert coincided with low progesterone (< 5 ng/ml), this alert was considered to be correct positive (CP), otherwise it was considered false positive (FP). When no oestrus alert was generated during an oestrus period determined by the progesterone profile, it was considered false negative (FN). Sensitivity (SN) was calculated as CP/(CP+FN) and positive predictive value (PPV) was calculated as CP/(CP+FP). Differences in SN and PPV between farms, activity tags (STL or STN) and housing condition (pasture or indoors) were examined using the Chi-square test for homogeneity.

Results: A total of 138 oestrus periods occurred during the pasture period and 95 oestrus periods occurred during the indoors period based on progesterone profiles. Overall sensitivity and PPV of the STL was 77.7% and 88.3% respectively. Overall sensitivity and PPV of the STN was 79.8% and 84.2% respectively. There was no difference in sensitivity and PPV between the tags. Differences between housing conditions were analysed per tag. Sensitivity and PPV did not differ between the pasture period (STL: 75.8% and 92.3%; STN: 82.1% and 87.6%) and the indoors period (STL: 79% and 85.8%; STN: 78.3% and 81.8%). Sensitivity and PPV did not differ between farms for the STL. For the STN no difference was found in sensitivity between farms. PPV of the STN did differ between farms (93.6% versus 79%, P<0.01).

Conclusions: The performance of the STL and STN are comparable. Although during the pasture period the basal activity of cows may differ from day to day, this does not affect the performance of the activity tags. Performance of the tags (i.e. PPV) differed between the two farms. This could mean that farm specific factors such as cow traffic, indoor housing conditions, herd management etc. cause more or less false positive oestrus alerts and therefore affect the performance of the tags in practice. Which factors play a role is an interesting area of further research.

RE1-023-002

Effects Of Hormone Treatment In Dairy Cows During The Early Puerperium On Fertility Parameters

Judith Krohn ^{1,*}, Axel Wehrend ¹, Susann Hass ¹, Plamen Georgiev ²

¹Clinic for Obstetrics, Gynecology and Andrology of Large and Small Animals, Giessen, Germany, ²Faculty of Veterinary Medicine, Thrakia University, Bulgaria

Objectives: Hormone treatments in the puerperal period are very popular but the effects documented in literature are controversial. In the presented study the effect of administration of PGF2α or gonadotropine releasing hormone up to 14 days post partum in cows with a physiological puerperium (pp) and a disturbed puerperium (dp) was investigated focusing on further puerperal development and fertility.

Materials and Methods: A total number of 305 cows was included in the study. The PGF2α group (pp1: n=65, dp1: n=41) was treated with 25 mg Dinoprost between 11-14 days post partum. The GnRH group (pp2: n=47, dp2: n=50) received 50 µg Gonadorelin and seven days later 25 mg Dinoprost during the same period after parturition. In the control group (pp3: n=48, dp3: n=54) 1 ml 0.9% Saline was administered between 11-14 days post partum. All injections were given intramuscular. A puerperal examination was done at the day of first treatment, between 25-31 days post partum and according to clinical signs. The body condition (bc) was measured by taking the back fat thickness at three defined periods. Milk production was estimated by calculating the mean daily production. For fertility parameters the data about all performed inseminations was utilized.

Results: Neither Dinoprost nor GnRH-treatment had a significant influence on puerperal involution of the uterus. No differences in all investigated fertility parameters were found. The effect of the hormone treatment on puerperal development and fertility was not influenced by milk production, bc or its decrease during early lactation. Cows with a higher bc shortly after calving had significantly less puerperal disturbances. Bc before calving had no effect on puerperal development or fertility. A distinct decrease of the bc early in lactation meant significantly less success in first insemination. Cows with a lower bc between 60-66 days post partum had a worse pregnancy rate.

Conclusions: The results indicate that no effect on puerperal development or fertility can be found in cows treated with Dinoprost or a combination of Gonadorelin and Dinoprost no matter if they showed a physiological or disturbed uterine involution.

RE1-023-003

The use of Fixed Time Artificial Insemination and re-synchrony in Southern Australian dairy herds

Matthew Izzo ^{1,*}, Mark Humphris ², Liz Pryor ³, Andrew Perry ⁴, Emma Bruce ¹, John Morton ⁵

¹The Vet Group, Allansford, ²The Milk Road, Newry, ³Boehringer Ingelheim Pty Limited, North Ryde, ⁴Kyabram Veterinary Clinic, Kyabram, ⁵Jemora Pty Ltd, Geelong, Australia

Objectives: The primary objective of the trial was to describe the reproductive performance of cows after fixed time AI with ovulation synchronisation and re-synchrony in Australian dairy herds, and to compare reproductive outcomes with conventional mating programs.

The secondary object was to compare conception rates between a novel intravaginal progesterone device (DIB-V® Boehringer Ingelheim) and another commercially available progesterone device (Eazi-Breed CIDR®, Zoetis).

Materials and Methods: The study was conducted between October 2014 and March 2015 on 2 seasonal calving commercial dairy herds located in the Murray region of Victoria. Herd 1 consisting of 475 dairy breed cows (Jersey, cross-bred and Holstein Friesian) and herd 2 consisted of 242 Holstein Friesian cows.

Within each herd in the dairy trial: group 1- oestrus detection and AI on detected oestrus for 33 days followed by a natural service period; group 2 – fixed time AI at day 0 followed by re-synchrony of all cows prior to ultrasound pregnancy diagnosis at day 30 and fixed time AI of cows diagnosed not pregnant at day 33 then natural mating; group 3- fixed time AI at day 0 followed by oestrus detection and AI on detected oestrus for 33 days then natural mating. An OVSYNCH-56 with progesterone (DIB-V for group 2 and CIDR for group 3) was used to synchronise oestrus for initial FTAI.

All data was entered into Excel (Microsoft Corporation, 2007) prior to analysis. Statistical analyses were performed using Stata 14 (StataCorp, College Station, TX). The following proportions were calculated: 3-week submission rate, 1st service conception rate, 6-week in-calf rate and proportion of cows that conceiving during the mating period. For proportions pooled over both herds in the dairy trial, confidence intervals were calculated for each group from predicted values after fitting the random effects models. Times to conception were analysed by survival analysis with the Cox proportional hazards models using the `-stcox` command in Stata 14. For the Cox models for the dairy trial, farm was fitted as fixed effect.

Results: Across both herds pooled, 1st service conception rates were similar for all 3 groups (47.77% vs. 51.57% vs. 47.75%) but were lower in herd 2 compared to herd 1. There was no difference in 1st service conception rates between the fixed time AI program that used the commercially available progesterone device- CIDR® (group 3) and the program that used the novel progesterone device- DIB-V® (group 2) (OR=1.15, 95% CI= 0.8-1.7, P-value= 0.459).

Across both herds pooled, there were no statistically significant differences in 6-week in-calf rates between the 3 groups (64.13% vs. 72.40% vs. 68.78%, P>0.05) but there was a tendency for group 2 to have a higher 6-week in-calf rate than group 1 (p=0.064).

Proportions of cows conceiving during the mating period did not differ significantly between the 3 groups (P>0.05) but were higher in herd 1 compared to herd 2. Survival analysis showed no difference in the hazard of pregnancy between the 3 groups. The observed median days to conception for cows that conceived were lower for groups 2 and 3 when compared to group 1 (1 day vs. 1 day vs. 10 days, respectively).

Conclusions: The results of this study showed that fixed time AI with ovulation synchrony and resynchrony combined with early ultrasound pregnancy diagnosis can result in similar first service conception rates, six week in calf rates and proportions of cows conceiving during the mating period to from programs which rely on oestrus detection, natural service or a combination of both.

The first service conception rates in groups 2 and 3 were similar showing that comparable conception rates can be achieved when using DIB-V® when compared to the CIDR® progesterone device for fixed time AI programs in Australian dairy cows.

RE1-023-004

Assessment of daily post partum change in proportion of cows positive to a commercially available test instrument designed to indicate endometritis.

Mick Clews^{1,*}

¹Vetora Reporoa, Reporoa, New Zealand

Objectives: As part of a larger study to look at the effect on reproductive outcome at the herd level of testing individual cows 8 to 28 days post partum (pp) for signs of endometritis and subsequent treatment of test positive (MC+) cows with a single intrauterine infusion of 500mg cephapirin (Metriclean™, Virbac) we first sought to assess the proportion of MC+ cows over the period 8 to 28 days pp.

Materials and Methods: A total of 15,336 lactating Dairy cows from 33 seasonally, spring calving herds on the Central Plateau region of New Zealand's North Island (average 465 cows per herd) were enrolled in the study. All cows were less than 29 days pp at time of enrolment. All herds were visited on three separate occasions at 21 day intervals being about 69, 48 and 27 days before the herd's next Planned Start of Mating. All cows greater than 7 days pp at the day of the visit were examined for signs of endometritis using the Metricheck™ device (Simcrotech, Hamilton, New Zealand) which consists of a 500mm stainless steel probe with a 40mm hemispherical rubber/silicon cup attached at one end used to sample the contents of the anterior vagina which is then assessed for pus as an indicator of endometritis). As visits to individual farms were 21 days apart, every cow was examined 8 to 28 days pp (inclusive). Presence of purulent or muco purulent material was considered to be MC+. The proportion of cows that were MC+ was calculated for each of the individual days pp.

Results: Of the 15,336 cows examined 2,721 (17.74%) were determined to be MC+. A scatter plot of proportion of cows MC+ against days pp (average daily n=730) showed little change (a very slight increase) in proportion of MC+ cows over the period 8 days to 18 days pp but a steady decline in proportion of MC+ cows in the period 19 days to 28 days pp. Logistic regression based on a split at 18 days pp showed that the daily change in the odds of being MC+ over the time period 8 days to 18 days pp was OR= 1.016 (0.9993-1.0336), p=0.06 on 8,576 observations. The daily change in the odds of being MC+ over the time period 19 days to 28 days pp was OR=0.9583 (0.9356-0.9815), p=0.00 on 6,760 observations. Although the daily change in the odds of being MC+ is relatively small it does accumulate over time. The odds ratio of a dichotomised analysis comparing the odds of being MC+ of the two groups of cows (8 to 18 days pp) and (19 to 28 days pp) was OR=0.7352 (0.6762-0.7993), p=0.00 on 15,336 observations (8,576 and 6,760).

Conclusions: The best chance of finding MC+ cows will come from making use of the period 8 to 18 days pp and thus require visits to herds at intervals of no longer than 11 days (14 days maybe most practical though). The carry on, larger study attempts to quantify the change in reproductive performance from treating these MC+ cows with intrauterine infusion of cephapirin (Metriclean, Virbac) with the aim to also determine if the change in odds of MC+ is likely to be due to decreased sensitivity of the test or genuine "self cure".

RE2-031-001

Production And Fertility Of Australian Carry-Over Cows

Andrew Hoare ^{1,*}, Kiro Petrovski ²

¹South East Vets, Mt Gambier, ²The University of Adelaide, Roseworthy, Australia

Objectives: The objectives of this study were to estimate the reproductive and milk production key performance indicators of cows with 'normal' or 'extended' (carry-over) lactation lengths on pasture-based farms in South Australia. Additionally, the life-time production for these cows was modelled using a hypothetical cow with 'normal' or 'extended' lactation length.

Materials and Methods: Data was collected from on-farm recording systems from 5 dairy enterprises. Statistical analyses were carried out using SAS version 9.3 software.

Cows were grouped into two treatment groups, cows with normal lactation length (≤ 305 -day lactation) and cows with extended lactation or carry-over cows (> 305 -day lactation). Milk production was estimated using modified Wood's lactation curve modelling. The effect of lactation length (normal or extended) on reproductive and milk production key performance indicators were estimated using analysis of variance or logistic regression. The reproductive key performance indicators included the inter-calving interval, waiting period, days open, number of inseminations, re-insemination patterns, 100-day submission and 200-day non-in calf rates.

The hypothetic cow produced the average milk yield per day according to her age and stage of lactation including all potential combinations calving interval of 365- (12 months) or 546-days (18 months) for a life in the herd up to her age of 10 years.

Results: A total of 39,170 and 3,712 cow-lactations were normal and extended respectively were included in the analysis. The inter-calving interval, waiting period, days open and number of services and re-insemination patterns differed between cows with normal or extended lactation lengths ($p < 0.001$). Naturally, the inter-calving interval, waiting period and days open were shorter for cows with 'normal' lactation length. The interesting findings include that cows with extended lactations had more inseminations per conception. The 100-day submission rate was higher in cows with normal lactation length and 200-day not-in-calf rate was lower. Interestingly, cows with a normal lactation had a smaller proportion of short returns compared to cows with extended lactations. Contrary, the rate of long returns was 76.5% for extended lactation cows in comparison to 56.2% in normal lactation cows. This may be a true situation or farmers and farm staff may become more sensitive to cows that have extended lactation and aiming to get them pregnant, submit them even if there is a slight suspicion of being in oestrus.

Average daily milk production was 31.5 and 18.7 L for the cows with normal and extended lactation lengths respectively ($p < 0.001$). The lifetime milk production per hypothetical cow decreased with each extended lactation from maximum 76,947 (8 calvings per cow of 10 years of age) to minimum of 48,124 L (4.5 per cow of 10 years of age; $p < 0.001$).

Conclusions: Cows with extended lactation have poorer reproductive and lactation performance than their counterparts with normal lactation lengths. Cows with extended lactation length appear to be less profitable than those with normal lactation length due to their lower levels of milk production per lifetime and poorer reproductive parameters.

RE2-031-002

Results of an investigation into Dairy Herd Bull Breeding Soundness and Management in Tasmania, Australia

Craig Dwyer ^{1,*}

¹President, Australian Cattle Veterinarians / Smithton Veterinary Service, Smithton 7330, Australia

Objectives: While many Australian dairy herds use a significant level of artificial insemination (AI) as part of their reproductive programs, most still rely on some natural service or bull matings in their herd. This project was aimed at identifying the current status of herd bull breeding soundness in the Tasmania dairy herd. Current practices in the management of dairy herd bulls on these properties and how these may be impacting on bull/herd fertility were also examined.

Materials and Methods: Sixteen dairy properties were selected from the Circular Head region in North West Tasmania. No selection criteria were imposed on the farms selected except that they would consent to all bulls used on their property during the breeding season undergoing a veterinary bull breeding soundness evaluation (VBBSE) and that farmers would complete a reproductive/bull management questionnaire relating to the same season.

In the period of 1 to 2 months prior to when the bulls were to be used in the herd all bulls were subjected to a standardised VBBSE on the property. This examination consisted of a general physical examination and a reproductive examination. Semen was examined crush side and a sample of the semen was also fixed and sent to a laboratory for sperm morphological analysis and live dead counts using nigrosin-eosin staining.

Bull results were collated into a report for farmers and bulls classified into three categories;

1. Fail/Cross - Not suitable for joining this mating period.
2. Qualified - Only suitable in multiple sire situations or with stipulations.
3. Pass/Tick - Suitable with no stipulations.

At the time of the testing farmers were also given a questionnaire relating to their herd reproductive management with an emphasis on bull management on their property. These surveys were collected, the data collated and analysed.

Results: There were 221 bulls tested as part of the project. As a result of the VBBSE, 52 (23.5%) of the bulls were assessed as a fail or high risk, a further 58 (26.2%) of the bulls were given a qualified pass. Therefore, as a result of the fertility examinations 110 (49.8%) of the bulls tested were considered at risk of being sub-fertile on the farms involved in the survey.

The reasons or risk factors for bulls failing the VBBSE or receiving a qualified pass were semen morphology and penile problems.

The herd sizes ranged from 180 to 940 milking cows. The average herd size in the project was 436 milking cows. The average percentage of bulls used with the milking herds was 2.74% with a range of 1.3 to 4%. The average percentage of bulls used with the heifers was 6.1% with a range of 1.3 to 12%. Bulls less than 2 years of age were used in 81% of herds. Bulls greater than 6 years of age were used in 19% of herds.

Of the surveyed herds, 94% used some sort of rotation program for their bulls whilst they were in the herd. Only 13% of the properties sampled had their bulls on the farm for greater than 1 month prior to use and 37% of the farms had their bulls arrive less than 2 weeks prior to being used.

Conclusions: This project illustrates that dairy herd bull fertility is an issue and that there are significant numbers of high risk bulls identified in

the study which will only be identified by a VBBSE that includes semen and sperm analysis.

There are several bull management practices which can be improved in the herds studied. These include improving vaccination and trace element programs for bulls, ensuring bulls arrive on farm earlier, the use of bulls 2 to 6 years of age and the correct percentage of bulls used in the milking herd.

RE2-031-003

Accuracy of diagnosing double corpora lutea and twin pregnancy in the first trimester of gestation in dairy cows

Zoltán Szelényi^{1,2,*}, Atilla Répási², Noelita Melo de Sousa³, Jean F. Beckers³, Otto Szenci^{1,2}

¹Department and Clinic for Production Animals, ²MTA-SZIE Large Animal Clinical Research Group, Szent István University-Faculty of Veterinary Science, Üllő, Dóra Major, Hungary, ³Fundamental and Applied Research for Animals & Health (FARAH), Laboratory of Animal Endocrinology, University of Liege, Faculty of Veterinary Medicine, Liege, Belgium

Objectives: The objective of this present study was to measure and evaluate the usefulness of measuring the P4 and bPAG-1 concentrations in cases of single vs. twin pregnancies and one vs. two corpora lutea at the first four months of gestation. We hypothesized that both the number of the corpus luteum and the number of fetus might have an effect on progesterone and pregnancy protein concentrations and we can set up clinically useful threshold levels in order to predict twin gestations.

Materials and Methods: Eighty-four Holstein-Friesian dairy cows were enrolled in this prospective observational clinical trial. Blood was collected at time-point 1: between Days 29 to 42, time-point 2: between Days 57 to 70, time-point 3: between Days 85 to 98, and time-point 4: between Days 113 to 126 of gestation, respectively and bPAG-1 and P4 concentrations were measured. The animal were grouped into three groups: singleton pregnancy with one corpus luteum (CON), singleton pregnancy with double corpora lutea (DCL), twin pregnancy with two corpora lutea (TWIN). All animals calved according to grouping. After ANOVA analysis animals were redistributed either according to number of corpus luteum or according to number of fetus. Blood samples were analyzed using RIA technique. Statistical analysis was carried out using the Minitab software.

Results: Binary logistic regression analyzing serum P4 concentrations differed at time-point 2 compared to baseline level, but the area under the curve (AUC) had low sensitivity. The bPAG-1 concentrations were statistically different at each time-point of gestation. The AUC cut-off values of serum bPAG-1 concentrations were sufficiently sensitive to differentiate between twin gestations from singleton ones. At time-points 3 (cut-off value of 3.4 ng/mL) and 4 (cut-off value of 56.5 ng/mL) statistically significant differences with low sensitivity, high specificity and a high AUC were found.

Conclusions: Based on these results the diagnosis of twin pregnancy using pregnancy protein measurements is clinically insufficient prior Day 85 of gestation, however the ability to confirm the early twin pregnancy diagnosis with bPAG-1 measurements appears to be promising. To achieve high sensitivity, further studies are required.

RE2-031-004

Associations Between Management Practices and Reproductive Performance in Canadian Dairy Herds

Jose Denis-Robichaud^{1,*}, Ronaldo Cerri², Andria Jones-Bitton¹, Stephen LeBlanc¹

¹Department of Population Medicine, University of Guelph, Guelph, ²Faculty of Land and Food Systems, University of British Columbia, Vancouver, Canada

Objectives: Many options are available to dairy producers for managing reproduction in their herd. Reproductive performance varies greatly from farm to farm, and it is unclear if reproduction management plays a major role in this discrepancy. The objective of this study was to identify management practices associated with reproductive performance on Canadian dairy farms.

Materials and Methods: A bilingual questionnaire was distributed online (FluidSurveys, Ottawa, Canada) and by mail to Canadian dairy farmers from March to May 2014 to assess farm management, as well as reproduction management practices. A total of 53 questions covered demographic information, general management on farm, reproduction management, and opinions and perceptions toward reproduction management. To describe their reproduction management practices, respondents were asked to give their percentage of artificial inseminations (AI) based on visual heat detection, timed AI program, or automated activity monitoring (AAM), for first and subsequent AI separately. The main management practice was defined as the practice used for > 50% of AI, or "combined" if no one practice was used for > 50% of AI. Pregnancy rate (PR), insemination rate (IR), and conception risk (CR) for 2013 were extracted from dairy herd information files (DairyComp 305, Valley Ag Software, Tulare, USA). Linear regression models adjusted for confounders were used to identify associations of these reproductive performance measures with farms' characteristics and management practices. Statistical analyses were conducted using SAS 9.3 (SAS Institute, Cary, USA).

Results: Approximately 9,000 invitations to participate to the survey were sent and a total of 833 surveys were completed (response rate: 9%). A total of 346 farms gave access to their herd files. The average (\pm SD) PR, IR, and CR were $17 \pm 4.7\%$, $43 \pm 11.3\%$, and $40 \pm 8.5\%$, respectively. Pregnancy rate ($\% \pm$ SE) was lower in tie stall barns (15.4 ± 0.7) than in free stall (17.6 ± 0.6), in herds inseminating once per day (16.6 ± 0.8) than in herds inseminating twice per day (18.1 ± 0.8), and in herds with < 100 lactating cows (16.2 ± 0.8) than in herds with more than 250 lactating cows (17.8 ± 0.8). Pregnancy rates were not significantly different by main reproduction management practice: visual heat detection (17.4 ± 0.6), TAI (18.4 ± 0.8), AAM (17.1 ± 1.3), or combined practices (18.2 ± 1.0). Insemination rates were lower in herds using visual heat detection (42.1 ± 0.7) than in herds using TAI (47.4 ± 1.1), or combined practices (46.9 ± 1.2), but not significantly different from herds using AAM (44.0 ± 1.6). Conception risks were higher in herds using visual heat detection (42.2 ± 0.6) than in herds using TAI (39.4 ± 0.8), but not significantly different from herds using AAM (39.6 ± 1.3), or combined practices (39.5 ± 1.0). Positive or negative opinions toward different management tools were not associated with reproductive performance.

Conclusions: Reproductive performance measured by PR, IR, and CR was influenced by factors other the reproduction management program. These findings suggest that different reproductive management programs can be as efficient, and efficiency can be achieved through other general management practices.

RE2-031-005

Survey on the reproductive management practices and performance of large-scale dairy farms in Hungary

 István Fodor¹; László Ózsvári¹

¹Department of State Veterinary Medicine and Agricultural Economics, Faculty of Veterinary Science, Szent Istvan University, Budapest, Hungary

Objectives: The reproductive performance of the Hungarian dairy cattle population has been continuously declining since the early 80's, despite the introduction of numerous new reproductive management techniques (e.g. OvSynch, pedometer). Therefore, the aim of our study was to survey the current reproductive management practices in the Hungarian dairy herds in order to give advice about how to improve their performance.

Materials and Methods: A survey was carried out in 34 large-scale dairy herds from all the statistical regions in Hungary between 22 May and 6 November 2015. Altogether 25,672 cows were surveyed in these herds, which cover 14.6% of the total Hungarian milk recorded Holstein-Friesian cow population. The average herd size was 755 dairy cows (range: 291-2,502) and the average 305-day milk yield was 10,014 kg (range: 8,330-12,541 kg). In each herd a questionnaire was used to collect the data. Firstly, the farm manager and/or the veterinarian were personally interviewed about the reproductive management practices in their herd, and secondly, the relevant data were gathered from the farm management computer programs. Our questions aimed at the number of animals in the different age groups, the herd-level reproductive indices (e.g. services per conception in cows, first service conception rate, etc.), and the reproductive management practices. Open questions were also included in the questionnaire, so respondents could depict the methods applied on their farms. Data and answers were recorded and evaluated by Microsoft Excel® program.

Results: A voluntary waiting period after calving was applied in 26 herds (76.47%), with an average length of 50.23 days (range: 30-80 days). Visual estrus detection (30 herds; 88.24%) was the predominant method of searching for cows in heat, activity monitoring devices were used in 23 herds (67.65%). In 27 farms (79.41%) estrous synchronization was performed, mostly OvSynch (20 herds; 58.82%). In 3 farms (8.82%) sexed semen was used in cows, but only in those showing intensive signs of estrus. Daily milk production was the most prevalent criterion in reproductive culling decisions (32 herds; 94.12%). Pregnancy was diagnosed 1.83 times per week on average, ranging from monthly (2 farms) to daily (4 farms) pregnancy checks. The average time of the first pregnancy check was 35.06 days after insemination (range: 27-60 days), which was performed via ultrasound in 23 herds (67.65%) and by laboratory PAG test in 2 herds (5.88%). Pregnancy diagnosis was confirmed 1.56 times on average (range: 0-3), typically at least at drying-off. In the majority of farms, efforts were made to protect milking cows from heat stress in summer (ventilator: 30 herds [88.24%]; sprinkling: 22 herds [64.71%]).

The average calving interval was 435 days (range: 392-490 days), average first service conception rate was 26.52% (range: 11.26-51.40%), and average services per conception (cows only) was 4.04 (range: 2.56-6.16), respectively. The breeding interval was 31.38 days (range: 22.00-56.03 days), and the proportion of reproductive culling was 31.68% out of all premature disposals (range: 7.57-69.70%), on average.

Conclusions: The results of our survey clearly showed that the stakeholders are willing to invest in order to improve the reproductive performance of their dairy herds. Practical reproductive management guidelines should be set up by experts that are adapted to the Hungarian circumstances, because the reproductive performance is not effectively monitored in many herds. It is not possible to quantify the pregnancy rate by most of the currently used farm management programs, however, it

is a basic parameter. The findings of the survey show that there is room for improving reproduction, thus, the competitiveness in the majority of the Hungarian dairy herds.

RE2-031-006

Time of ovulation relative to onset of oestrus as determined by visual observation and Heatime™ activity meters in loose housed Hereford cattle

 Sindre Nelson¹; Caroline Haadem¹; Anna Hessle¹; Ane Nødtvedt¹; Adam D. Martin^{1,*}

¹Department of Production Animal Clinical Sciences, Norwegian University of Life Sciences, Oslo, Norway

Objectives: The aim of this study was to investigate the time from oestrus detection using both visual and a commercially available heat detection system (Heatime™) to ovulation in housed purebred Hereford cattle.

Materials and Methods: This study was performed at the Götala Beef and Lamb Research Centre, Sweden between 01/06/15 and 03/07/15. The study consisted of 37 purebred female Hereford beef cows (14 nulliparous 23 pluriparous) which were housed in loose housing on deep straw bedding. The primiparous animals were all aged between 13 and 15 months at the start of the experiment and had a mean weight of 407 Kg. The animals had a modal body condition score of 3.5 (range 2.5 to 4.0).

Blood samples were taken thrice weekly from all study animals. Serum was extracted, frozen and analysed for progesterone concentration using an ELISA (Ridgeway Scientific UK). Luteal activity was defined progesterone concentration >1 ng/ml.

Visual observation of oestrus was performed for 20 minutes thrice daily at 0600, 1400, and 2200. When a behaviour associated with oestrus was observed a score was assigned to that cow, when the scores summated to 100 or more the cows were deemed to be in oestrus (Van Vliet, 1996). A commercially available oestrus detection system Heatime was according to the manufacturer's guidelines.

Once oestrus was detected cows reproductive tracts were examined thrice daily (after the oestrus observation period) using real time ultrasonography to determine the time of ovulation.

Results: Oestrus was not detected in 8 (4 nulliparous and 4 multiparous) animals. The progesterone concentration in these animals did not rise above 1 ng/ml for two consecutive progesterone measurements and were therefore deemed to be in anoestrus throughout the study period.

In total there were 46 oestrus events with recorded ovulations (40 visually detected oestrus and 46 detected with Heatime™). There were 40 visually detected oestrus with determinable ovulation. The mean time from visual oestrus detection to ovulation was 19.7 hours (95% confidence interval 15.8 – 23.6 hours). In nulliparous animals (n=16) the mean visual oestrus to ovulation interval was 16.8 hours (8.6-24.9 hours). Whilst in multiparous animals (n=24) the mean visual oestrus to ovulation interval was 21.7 hours (17.7 - 25.6 hours).

There were 46 oestruses with determinable ovulation detected by Heatime™. The mean time from visual oestrus detection to ovulation was 21.6 hours (95% confidence interval 18.1 – 25.0 hours). In nulliparous animals (n=16) the mean visual oestrus to ovulation interval was 21.3 hours (15.7 - 26.8 hours). Whilst in multiparous animals (n=30) the mean visual oestrus to ovulation interval was 21.7 hours (17.2 - 26.3 hours).

Conclusions: Whether visual oestrus detection or Heatime™ oestrus detection is used there is no practically important difference in time from oestrus detection to ovulation. When either method of oestrus detection is used nulliparous animals had a numerically shorter interval from oestrus detection to ovulation. However, the difference is so small that practically the same protocol should be used irrespective of whether the animal to be inseminated is nulliparous or multiparous

RE2-031-007

Effect of GnRH administration at initiation and eCG at the end of a 7 Day-Co Synch+progesterone program for FTAI on pregnancy rate in beef cows

Federico Randi ^{1,2,*}, Patrick Lonergan ¹, Alessio Valenza ³, David Kenny ²

¹School of Agriculture and Food Science, University College Dublin, Dublin, ²AGRIC Teagasc Grange, Teagasc, Dunsany Co Meath, Ireland, ³CEVA Sante Animale, Libourne, France

Objectives: The objective of this study was to compare the effectiveness of three different oestrous synchronisation protocols to facilitate fixed time artificial insemination (FTAI) in suckler beef cows under Irish pasture-based field conditions.

Materials and Methods: A total of 1410 suckled cows located on 61 farms were enrolled across two replicates (in Spring, S, n=703 and Autumn, A, n=707). After a voluntary waiting period of 35 days postpartum, all cows were ultrasound scanned to determine the presence or absence of a corpus luteum (CL) and body condition score (BCS) was recorded on a scale of 1 to 5. Cows were then randomly assigned to receive a 7 day progesterone-releasing intravaginal device (PRID E®) without (Group 1) or with (Group 2) a GnRH analogue (Ovarelin®) at PRID insertion and a luteolytic dose of prostaglandin F2α (Enzaprost®) at PRID removal. A third group of cows received 400 IU equine chorionic gonadotropin (eCG, Syncrostim®, Group 3) at PRID removal.

After 72 h from the PRID removal GnRH was administered and all cows were inseminated. Pregnancy diagnosis was carried out 35-40 days after FTAI by transrectal ultrasonography. Data were analyzed using the GENMOD procedure of SAS.

Results: There was a significant treatment by season interaction for pregnancy rate (P=0.0002). In Spring, overall pregnancy rate was 59.1% (416/703) and was affected by treatment (49.6 v 59.3 v 68.5%, for Groups 1, 2 and 3, respectively P<0.05). In contrast, in Autumn, overall pregnancy rate (52.6%, 364/707) was unaffected by treatment (53.7 v 52.0 v 48.7%, respectively). Presence of a corpus luteum at initiation of treatment (S 50.6%; F 70.0%) increased pregnancy rate independently of treatment and season (P=0.03). The mean BCS in S=2.75 and A=2.92 was not different, but BCS positively affected pregnancy rate independently of treatment or season (P=0.003).

Conclusions: The administration of GnRH at the initiation of a 7 day Co-Synch+PRID E protocol and the supplementation of 400 IU of eCG at PRID E removal, both increased pregnancy rate in Spring calving suckled beef cows. This effect was not evident in Autumn calving cows. Seasonal differences in outcome may be reflective of different managements (grazing v confinement), interval post-partum AI or breed type and remain to be elucidated.

SR1-020-001

Development of an ovine model of digital dermatitis infectionJarlath Nally^{1,*}, Jennifer Wilson-Welder¹, David Alt¹, Paul Plummer²¹Infectious Bacterial Diseases, USDA, ²Veterinary Diagnostic and Production Medicine, Iowa State University, Ames, IA 50010, United States

Objectives: Digital dermatitis is an infectious cause of lameness primarily affecting dairy cattle, but also beef cattle, sheep, goats, and more recently, in a small population of North American wild elk. Digital dermatitis is associated with a mixed bacterial infection, including several *Treponema* species, and other aerobic and anaerobic bacterial species. Whilst the exact etiology has not been demonstrated, a number of bacterial, host and environmental factors contribute to disease development and progression. In order to study host-bacterial interactions and develop effective therapeutics, a reproducible laboratory model of infection is required.

Materials and Methods: Crossbred sheep of mixed ages were obtained from a breeding flock free of hoof disease. Hind feet were abraded to create a superficial wound before wrapping to emulate a moist, anaerobic environment, similar to that believed to predispose animals to infection. After 3 days, wounds were inoculated once (in a final volume of 1ml) to macerated lesion material from active cases of bovine digital dermatitis and remained wrapped, with periodic rewetting. Animals were monitored for lameness and lesion development for several weeks.

Results: Experimentally inoculated hind feet developed lesions indicative of infection by two weeks post-infection. At this time, swabs of lesions were positive for the presence of spirochetes as observed by dark-field microscopy. At four weeks post-infection, histologic changes in the dermis and epidermis were consistent with those described for bovine digital dermatitis, including erosion of the keratin layer, ballooning of underlying keratinocytes and neutrophil dominated inflammatory infiltrate. Silver staining of lesion biopsies at four weeks confirmed that spirochetes penetrated host tissue. Biopsied material was subsequently used to reproduce and maintain infection in naïve sheep, predisposed as described above.

Conclusions: Digital dermatitis is an infectious disease that can be reproduced in experimentally infected sheep. The continued development and refinement of this ovine model of digital dermatitis will allow for novel insights into pathogenic mechanisms of infection, as well as the development of improved diagnostic and therapeutics.

SR1-020-002

Prevalence, clinical findings and progression of extensive fibrinous pleurisy in adult sheep based upon ultrasonographic examination of the chest.Phil Scott^{1,*}¹Capital Veterinary Services, Haddington, United Kingdom

Objectives: The objective of this study was to investigate the prevalence, clinical findings and progression of fibrinous pleurisy lesions in adult sheep in the United Kingdom following initial ultrasonographic diagnosis.

Materials and Methods: Fibrinous pleurisy in sheep cannot be reliably diagnosed on auscultation of adventitious sounds alone therefore the

initial screening process involved examination of both sides of the chest using a 6.5 MHz microconvex probe connected to a real-time, B-mode ultrasound machine. All adult sheep in four flocks (comprising 350, 500, 700 and 850 breeding ewes, respectively) screened for ovine pulmonary adenocarcinoma (OPA) during autumn 2015 were also examined for fibrinous pleurisy. Sixty five adult sheep presented to the University of Edinburgh Veterinary School's Farm Animal Hospital (FAH) over a two years' period 2013-5, where the cause of illness was not readily established, were scanned for lesions of the lungs/pleurae.

Results: Two sheep with extensive unilateral fibrinous pleurisy were identified in the 700 ewe flock during the OPA screen; neither sheep showed signs of illness. Three sheep with fibrinous pleurisy were diagnosed ultrasonographically in the FAH and presented with chronic weight loss (2) while one ewe presented with an increased respiratory rate, abdominal breathing and weight loss. Auscultation in all cases revealed absent normal breath sounds and greatly reduced heart sounds on the affected side of the chest with increased wheezes and louder heart sounds on the unaffected side. No pleuritic rubs were heard. Procaine penicillin administration daily for four weeks coincided with rapid resolution of lesions within two weeks except for one ewe where the pleurisy extended to 15 cm and appeared well encapsulated. The extensive fibrinous exudate extending >8 and 10 cm in two recovered sheep appeared as discrete 3-4 cm spherical hypochoic areas when re-scanned two weeks after treatment commenced and these lesions could not be differentiated ultrasonographically from an abscess.

Conclusions: This is the first report of ultrasonographic monitoring of an extensive fibrinous exudate within the pleural space of sheep which was not detected during thoracic auscultation. None of the six sheep was sick nor showed signs of acute respiratory disease. The efficacy of antibiotic therapy could not be assessed because no animal was left untreated but the rapid resolution of extensive fibrinous exudate in three sheep would suggest some beneficial effect. The discrete spherical hypochoic area in the pleural space observed two weeks after initial diagnosis could not be differentiated ultrasonographically from an abscess.

SR1-020-003

The impact of infection with Schmallenberg virus on weaning rate in Irish sheep flocksDamien Barrett^{1,*}, Donal Sammin², Ronan O'Neill², Tracy Clegg³, Simon More³¹Sligo RVL, Dept of Agriculture, Food and the Marine, Sligo, ²Central Veterinary Laboratory, Dept of Agriculture, Food and the Marine, ³Centre for Veterinary Epidemiology and Risk Analysis, University College Dublin, Dublin, Ireland

Objectives: In Ireland, SBV was subsequently confirmed by RT-PCR in 49 cattle herds and 39 sheep flocks in 2012 and 2013. While these studies provide a good representation of the spatial distribution of SBV in Ireland, they do not quantify the impact of SBV on productivity. The objectives of this study were to assess the impact of SBV on weaning rate in Irish sheep flocks, based on data reported by Irish sheep farmers, and to evaluate weaning rate in sheep flocks as an indicator to be used in emerging disease surveillance systems.

Materials and Methods: A questionnaire on productivity and management practices in sheep flocks was developed. These questionnaires were distributed among sheep farmers where SBV had been confirmed and through farmer discussion groups. Valid responses from 267 sheep farmers were received. Excel 2007 (Microsoft, USA) and

transferred into Stata SE 12 (Statacorp, USA) for analysis. Univariate and multivariate negative binomial regression model was carried out on the data. Maps were created using ESRI Arcview 3.2 (Redlands, California), with flock location determined using the geo-coordinates maintained by the DAFM national herd database.

Results: Group 1 flocks (with a laboratory confirmed case of SBV) had a weaning rate approximately 90% that of the control Group 4 flocks (negative flocks in a county where SBV had not been diagnosed). The weaning rate among mountain breeds of sheep was approximately 90% that of lowland breeds, where there was a mixture of lowland and mountain sheep, the weaning rate was approximately 95% that of lowland sheep. For each unit increase in flock ewe barren rate, the weaning rate was 0.39 times lower than that of a flock with no barren ewes. Similarly, for each unit increase in 2012 flock weaning rate, the flock 2013 weaning rate was 1.65 times greater. Examination of the residuals indicated that there was no significant lack of fit in the final model and no significant outliers.

Conclusions: The 10% reduction in weaning rates as a result of where the presence of SBV was confirmed is a justifiable concern for sheep farmers. Several other factors relating to management and breeding were also found to significantly affect weaning rate. As there was no pre-existing production database in existence, the data had to be collected by questionnaire. In a broader context, this study shows the value of interrogating production data in conjunction with an animal disease database in estimating the economic impact of an emerging disease.

SR1-020-004

A study on tuberculosis in camelids in Al-Muthanna governorate /Iraq

Karima Al Salihi ^{1,*}

¹Veterinary Internal Medicine, College of Veterinary Medicine, Al Muthanna University, Iraq, Samwah, Iraq

Objectives: There is a total of 58,000 camels in Iraq, according to the FAO statistics of 2011 (Tara, 2011). The extent of TB has been well documented in humans and most domestic animals in Iraq and according to the latest WHO data published in may 2014 Tuberculosis deaths in Iraq reached 928 or 0.63% of total deaths. However, very little is known about the epidemiology and cause of camel TB in Iraq. Therefore, this study was intended to investigate the epidemiology of camel TB based on gross pathology and identify its causative agents using mycobacteriological culturing, and multiplex polymerase chain reaction (PCR) in Al-Muthanna governorate in Iraq.

Materials and Methods: A cross sectional study was conducted on 50 apparently healthy camels male (n=25) and female (n=25) slaughtered at Al Muthanna abattoir. For each animal, post-mortem examination was performed according to routine procedures. Mandibular, retropharyngeal, bronchial, mediastinal, mesenteric and hepatic lymph nodes were examined. Lungs, liver, small intestine and kidneys were also examined in detail. The suspected lesions on both left and right lungs were sectioned, inspected and palpated carefully. Whenever gross lesions suggestive of TB were detected in any of the tissue, the tissue was classified as having lesions. For mycobacteriological culturing, samples were cultured on Lowenstein Jensen (LJ) medium on duplicate slants, one enriched with sodium pyruvate and the other enriched with glycerol. Cultures were incubated aerobically at 37°C for 8–12 weeks with weekly observation for growth of colonies. Positive cultures were confirmed with Ziehl Nelsen staining and preserved with freezing media. The multiplex

PCR differentiate *M. tuberculosis* complex from *M. avium* complex, *M. intracellulare* and other mycobacterial species. Multiplex polymerase chain reaction (PCR) was done for all isolated bacteria.

Results: The distribution of lesions and the severity of the disease were established in the 24 camels with suspicious lesions. The TB lesions were seen in the lymph nodes and lung lobes of the examined animals. On the basis of gross pathology, the prevalence of camel TB was 48 % (24/50). The mycobacterial growth was confirmed in 50 % (12/24) of the samples collected from camels with grossly suspicious TB lesions. Mycobacterium genus typing was conducted on the 12 culture isolates from camels. Based on multiplex PCR using the primers of the *M. tuberculosis* complex and *M. avium* complex, 9 isolates gave signal to the genus *Mycobacterium*.

Conclusions: The results of the present study have shown that the camel TB lesions are caused by mycobacteria other than *Mycobacterium tuberculosis* complex. The author, hence recommended further identification and characterization of these species, which would be useful towards the efforts made to control TB in camels.

SR2-021-001

Sheep And Farm Level Factors Associated With Contagious Ovine Digital Dermatitis: A Longitudinal Repeated Cross-Sectional Study Of Sheep On Six Farms

Joseph Angell ^{1,*}, Dai Grove-White ¹, Jennifer S. Duncan ¹

¹Epidemiology and Population Health, The University of Liverpool, Neston, United Kingdom

Objectives: Contagious ovine digital dermatitis (CODD) is a cause of severe lameness in sheep in the UK currently affecting approximately 50% of farms. The epidemiology is poorly characterised and there have been no on farm studies investigating risk factors for CODD. The aims of this study were to investigate 1) the prevalence dynamics of CODD, 2) the association between sheep with CODD and potential risk factors and 3) the impact of CODD on lameness in sheep.

Materials and Methods: Six farms with CODD were studied in North Wales. The farms were visited at two-month intervals between June 2012 and October 2013. At each visit all lame sheep and randomly selected non-lame sheep were examined (ratio 1-3) resulting in a total of 6,515 sheep examined. Descriptive statistics, together with logistic regression modelling techniques employing probability weights were used to describe the prevalence of CODD within and between farms and to investigate temporal variations as well as farm, environment and sheep level risk factors associated with CODD.

Results: The prevalence of CODD varied between farms (2.5-11.9%). Within farms, prevalence may increase in the early autumn and after housing. Environmental risk factors included poached pasture. Co-infection with footrot was strongly associated with CODD OR: 7.7 (95%CI: 3.9-15.5 P<0.001) but negatively associated with co-infection with interdigital dermatitis (ID) OR: 0.04 (95%CI: 0.02-0.1 P<0.001). Reinfection with CODD was observed in 78 individuals but there was no re-infection at foot level.

Lameness on all farms reduced during the study and seasonal changes in lameness followed similar patterns to those for CODD. Infection with CODD leads to a greater increase in locomotion score compared to footrot or ID and CODD lesion grade was strongly associated with being lame. Sheep with CODD in more than one foot were more likely to be

lame OR: 25.0 (95%CI: 12.5-49.9 P<0.001) than those with just one foot affected OR: 10.0 (95%CI: 8.6-11.6 P<0.001).

Conclusions: The biggest risk factor for CODD was co-infection with footrot and thus control of footrot may help reduce the risk of CODD on affected farms. Environmental risk factors for CODD were similar to those for footrot adding weight to control strategies that target both diseases in tandem. This disease whilst currently identified only in the UK and Ireland causes severe welfare implications for affected sheep. This paper highlights key risk factors which may assist in developing control strategies.

SR2-021-002

Efficacy of Chitosan, a Natural Polysaccharide, against *Cryptosporidium Parvum* Infection in Vitro and in Vivo in Small Ruminants

Karim Adjou ^{1,*}, Jean-Philippe Marden ², Eric Auclair ³, Aurélie Grasset Chevillot ⁴, Isabelle Vallee ⁴

¹Ecole Nationale Vétérinaire D'Alfort, Maisons-Alfort, ²Philleo Lesaffre, Marcq-En-Bareuil, ³Philleo Lesaffre, Marcq-En Broeul, ⁴Umr Bipar Anses-Enva-Inra, Maisons-Alfort, France

Objectives: Cryptosporidiosis is a zoonotic disease caused by a protozoan parasite, *Cryptosporidium parvum*. In animals, it is considered as an economically important disease with clinical signs and death in young ruminants. The usual clinical course is acute diarrhoea affecting animals from 1 to 3 weeks old. Today, no drugs are fully effective in the treatment of cryptosporidiosis in man and animals. Therefore the research for new therapeutic agents is crucial.

Materials and Methods: We report here details of the adaptation of in vitro culture systems (HCT-8 and Caco-2 cell lines) for *C. parvum* to investigate the "anticryptosporidial" activity of drugs and the results obtained with two new molecules (Chitosan NAG and Chitosan Mix).

Chitosan is a sugar that is obtained from the hard outer skeleton of shellfish, including crab and shrimp. It is used for medicine. Chitosan, a natural polysaccharide compound, has been found to be active against a variety of diseases including antimicrobial and antitumoral effects. We investigated the effects of Chitosan in our two in vitro models we established in the laboratory. Paromomycin, a classical drug used in veterinary medicine, was used as a positive control. Immunofluorescence technique was used for the identification and enumeration of the parasites.

Results: Our results showed a very significant reduction of viability of *Cryptosporidium* oocysts (>95%) (in comparison with non treated samples) after pre-incubation of 24h at 37°C with Paromomycin (P < 0.001), Chitosan Mix and Chitosan NAG (P < 0.001). On the other hand, Paromomycin, Chitosan Mix and Chitosan NAG inhibited significantly the development of *Cryptosporidium parvum* in HCT-8 and Caco-2 cell lines (P < 0.005). These effects are dose-dependent. Synergic effects were obtained when Chitosan NAG treatment was associated with Paromomycin.

Conclusions: In conclusion, these findings provide for the first time the evidence of in vitro inhibitory activities of natural polysaccharides against *C. parvum*. The efficacy of Chitosan was evaluated in goat neonates experimentally inoculated with *Cryptosporidium parvum* oocysts per oral route. The preliminary results showed the efficacy of chitosan in reducing oocyst shedding and diarrhoea in goat kids cryptosporidiosis.

SR2-021-003

An outbreak of *Anaplasma phagocytophilum* in a goat herd in the Province of Trento (North-eastern Italian Alps): a case report

Sabrina Paternolli ¹, Stefania Villotti ², Paola Landi ³, Giovanna Minghetti ⁴, Sara Carlin ¹, Elena Porcellato ¹, Graziana Da rold ¹, Anna Granato ¹, Laura Lucchese ¹, Alda Natale ¹, Silvia Ravagnan ¹, Debora Dellamaria ^{1,*}

¹Istituto Zooprofilattico Sperimentale delle Venezie, padova, ²Practitioner, ³APSS servizio veterinario di Trento, ⁴Fondazione Edmund Mach, Trento, Italy

Objectives: *Anaplasma phagocytophilum* (AP) is an emerging tick-borne bacterium with both veterinary and human health implications. AP is spread over a wide territory of the USA, Europe and Asia vectored by ticks of the genus *Ixodes*. The disease in domestic ruminants, also called tick-borne fever (TBF), has been recorded most frequently in cattle and sheep; while poor data on clinical cases of TBF associated with naturally acquired infection is available in goats. This case report describes the first evidence of a severe AP outbreak in naturally infected goats in the Province of Trento (North-eastern Italian Alps).

Materials and Methods: In June 2015 the farm veterinarian reported a febrile syndrome in five lactating goats at pasture characterized by high temperature (>40°C), apathy, poor appetite, sudden drop in milk production associated with an increase of the somatic cell count and hyperaemic stains on udder skin. Within the following 3 weeks approximately 90/200 lactating goats (45%) showed similar symptoms. Most of the affected animals recovered spontaneously in 2-4 days without therapy; 10 of them presented diarrhoea and 4, among the older ones, died. Clinical signs appeared only in grazing lactating goats and the farmer reported that 4-5 ticks were removed per goat daily. For the first diagnosis whole blood samples and sera of 2 recovered and 3 symptomatic animals were tested for haemoparasites (AP, *Babesia* spp. and *Theileria* spp.) using PCR assays (Massung & Slater, 2003; Casati et al., 2006) and for AP antibodies by an immunofluorescence assay (IFAT) using the cut-off titre of 1:80 for both IgG and IgM. After the outbreak, 22 adult goats were randomly selected to investigate patterns of AP infection within the herd. Animals were kept under observation for clinical signs and molecular and serological investigations on blood samples, collected in July and in September 2015, were performed. On September 2015 questing ticks (73 nymphs and 9 larvae) were also collected from the pasture by standard blanket dragging. The ticks were pooled into pools of five and molecularly examined for AP. Some representative positive samples were sequenced to perform a phylogenetic tree.

Results: Molecular investigations revealed the presence of AP in each goat tested for the first diagnosis and only one showed specific IgG antibodies (1:80). In July 8/20 (40%) goats tested positive for AP in blood samples by PCR and 15/20 (75%) had IgG antibodies against AP with titre ranging from 1:160 to 1:2560. In September only 3/22 (9%) animals resulted positive for AP by PCR and 9/22 (41%) goats resulted positive for IgG antibodies against AP with titre ranging from 1:160 to 1:5120. Among 8/20 goats positive for AP, 4 heads showed drop in milk production, 3 have had symptoms in July and 1 was apparently healthy; at the second sampling only one animal tested positive again by PCR and 7 goats became negative. Antibody titres showed a progressive decline in each seropositive animal but 3 heads: one goat developed antibodies and 2 presented an increase in antibody titre at the second sampling. Questing ticks collected at the pasture were identified as *Ixodes ricinus* and 2 pool of nymphs resulted positive for AP, showing a minimum infection rate of 2.4%. However the tick infection rate at the time of transmission remains unknown. The sequences obtained from blood and tick samples were identical to each other and clustered with the Italian, Polish, American and Japanese strains (KJ663729, EF143803, JQ063013 and FJ600591).

Conclusions: To our knowledge this report is the first case of a severe AP outbreak in naturally infected goats. The high number of animals with clinical manifestations in the same herd was unexpected and has led to significant economic losses. Since an iatrogenic transmission was excluded, our findings suggest a focus of a highly pathogenic AP strain or an outbreak characterized by a high infection rate in ticks and in wildlife. Further investigations in this goat herd are ongoing in order to study the bacteraemia and antibody dynamics over time. The results will give new information on possible chronic infections and clinical relapses in goats.

SR2-021-004

Staphylococcus aureus in Dairy Goats and Human Milkers in North Carolina (USA)

Rachael Kearns ¹Roberta Lyman ¹Kevin Anderson ^{1,*}¹Population Health & Pathobiology, College of Veterinary Medicine, NC State University, Raleigh, United States

Objectives: The objective was to determine the prevalence of *Staphylococcus aureus* in aseptically collected milk samples and nasal swabs from lactating dairy goats and from the nose and hands of individuals milking the goats. We determined the % presence of *S. aureus* in samples from the various sites and compared antibiotic susceptibilities and genotypes of the *S. aureus* isolates. Herd characteristics and management practices were obtained from surveys completed on each dairy.

Materials and Methods: Samples were collected (September of 2014 to July of 2015) from 30 NC properties with dairy goats. The total included 519 milk samples, 502 goat nasal swabs, and 97 human swabs. Dairy goats were found on properties that ranged from small backyard to larger commercial operations. Aseptically collected milk and nasal swab samples were obtained from all milking does. Hand and nasal swab samples were collected from individuals milking the goats. For each herd, data was collected on animal numbers and on the herd's milking and mastitis control practices.

Milk samples (0.1 ml) were plated and bacteria present identified using procedures consistent with NMC recommendations. Swab samples were macerated in 0.85% sterile saline and 1 ml plated on 3M Staph Express Petrifilm plates according to manufacturer's instructions. Antibiotic susceptibilities for the *S. aureus* isolates were determined using the Kirby-Bauer method according to Clinical Laboratory Standards Institute (CLSI) protocol. Genotyping was accomplished by PFGE using US Centers for Disease Control (CDC) protocols with minor modifications, and PFGE gels were analyzed and dendrograms constructed using BioNumerics software.

Results: A major finding of the study was that *S. aureus* was infrequently a cause of IMI (1.2% of all milk samples) in the NC herds studied. In contrast, nearly half (46.2%) of all goat nasal swabs were *S. aureus* positive. Approximately one-fourth of human nasal and hand swabs were positive for *S. aureus* (25.8%). Preliminary PFGE analysis reveals some sharing of *S. aureus* genotypes between goats and humans and possibly other animals. Some isolates of *S. aureus* from goats displayed evidence of multi-drug antimicrobial resistance.

Surveys indicated that most goat owners consumed raw milk from their goats. Some owners made cheese from the milk. Most farms milked their goats twice a day, either by machine, by hand, or both. Only rarely did producers report wearing gloves during the milking process. A variety of procedures were used in pre-milking preparation, but all producers used post-milking germicidal teat dips/sprays.

Conclusions: *Staphylococcus aureus* was infrequently (1.2%) isolated from milk samples of NC dairy goats, but was commonly detected (46.2%) in goat nasal swabs. Only some goats with *S. aureus* displayed multi-agent antimicrobial resistance. Goat owners appear to be successful in minimizing the presence of *S. aureus* as a cause of IMI.

SR2-021-005

Comparative effects of Border Disease Virus genotypes on ovine fetal infection

Marie-Anne Bethune ^{1,*}Herve Cassard ²Angelique Teillaud ³Gilles Meyer ²¹INP-ENVT College of Veterinary Medicine of Toulouse - France, Toulouse, France, ²Ruminant section, Department of Livestock and Products - Veterinary Public Health, INP-ENVT College of Veterinary Medicine of Toulouse - France, ³UMR1225 IHAP, INRA, Toulouse, France

Objectives: Border Disease is a worldwide disease of sheep caused by Border Disease Virus (BDV). With 7 phylogenetic groups, the BDV genetic diversity is large but its impact on pathogenesis is not well understood. In France four BDV genotypes, 3, 4, 5 and 6, have been identified since the first description of BD in 1984. Only BDV-3 and BDV-6 genotypes seem to be responsible for a recent French severe epizootic. The objectives of this study were to compare, in a same ovine model, the pathogenesis of the four French BDV genotypes. Fetal infections, ability to induce abortions, fetal malformations and production of permanent infected lambs were recorded.

Materials and Methods: Animal experimentation was performed under EEC guidelines (86/609/CEE) and official French ethical agreement. Four groups of 8 pregnant ewes at 52 days of gestation and free of pestivirus (negatives for both antibodies and BDV) were inoculated (Day 0) by the intramuscular route with 2.105 TCID₅₀/animal of BDV-3, BDV-4, BDV-5 and BDV-6 genotypes, respectively. BDV-5 AV was the first strain isolated in France in 1984. BDV-3 10405 and BDV-6 6390 strains were isolated in 2010 from recent French BD epizootic. BDV-4 IZ strain was isolated from an izard (*Rupicapra pyrenaica*) and recently detected in French Pyreneans sheep. A fifth control group was not infected. Complete clinical examinations of ewes were recorded daily from 3 days before inoculation (D-3) to D18 post-infection and for abortion until the end of the experimentation. Haematological examination was performed every other day from D-3 to D18 using a Melet Schloesing 9-5 analyzer. Viral infection of ewes was examined in blood EDTA samples from D-1 to D18 by real-time reverse transcription-PCR (RT-qPCR, Taqvet pestivirus, Life Technologies), and antibody response kinetics was measured by NS2-3 ELISA (Life technologies) and seroneutralisation every week until D64. The ewes were euthanized two months after challenge (D64) at 117 days of pregnancy. Fetuses were immediately collected, examined for viability, malformations, growth retardation (atlas-tail base, radius and tibia lengths), antibody status (NS2-3 ELISA and neutralisation assays) and BDV presence in the brain, thymus and spleen (RT-qPCR, Life Technologies).

Results: No clinical signs were observed in ewes after infection except in the BDV-5 group which showed moderate depression at D8 and D9 (all animals). Infections with each genotype were followed by a significant transient leucopenia from D3 to D7, mainly characterized by lymphopenia. Lymphopenia was more severe for the BDV-4, BDV-5 and BDV-6 groups but with no significant differences (Anova) when compared with BDV-3 group. Virus could be detected in 5, 6, 8, and 5 sheep of BDV-3, BDV-4, BDV-5 and BDV-6 groups, respectively with

a mean duration of 1.2, 1.4, 4.2, and 1.4 days, respectively. Abortion was observed only in two BDV-5 inoculated sheep. At the end of the experiment, 14, 17, 20 and 12 fetuses were collected in the BDV-3, BDV-4, BDV-5 and BDV-6 groups. Large differences were observed for gross examination of fetuses. In the BDV-5 group, 62.5% of fetuses died and 8.3% of live fetuses had malformations (arthrogryposis, hydrocephalus, cerebellar atrophy). The BDV-4 and BDV-6 groups contained only viable fetuses but with malformations for 58.8% and 10% of them, respectively. Neither lethality nor malformations were found in the BDV-3 group. In contrast BDV loads (as measured by RT-qPCR) were similar in all groups. All fetuses except one BDV-3 sheep were indeed positive for presence of BDV in at least one tissue sample. Mean viral loads were 4.7, 5.5, 5, 5.8 and 4, 3.4, 3.8, 4.6 log₁₀ RNA copies/100 mg of tissue for brain and thymus of BDV-3, BDV-4, BDV-5 and BDV-6 groups respectively. Differences (anova) were only significant between BDV-5 and BDV-4.

Conclusions: This study shows that strains of the four BDV genotypes harbor the same ability to infect pregnant ewes and pass through the placenta to infect fetuses. However, differences were observed between genotypes in their ability to induce fetal death and abortion, fetal malformation or growth retardation. These results must be taken into consideration when testing efficacy of vaccines to prevent production of permanent infected lambs. Further studies are warranted to assess the mechanisms of fetal pathogeny. The genome of each BDV strain was just fully sequenced and the comparative results will be discussed (data not shown).

SR2-021-006

Elimination of virulent strains (aprV2) of *D. nodosus* from feet of 28 Swiss sheep flocks – a proof of concept study

Deborah Greber ^{1,*}, Gertraud Schüpbach ², Giochen Bearth ³, Rita Lüchinger ⁴, Adrian Steiner ¹

¹Clinic for Ruminants, ²Veterinary Public Health Institute, Vetsuisse-Faculty, Bern, ³Veterinary Office of the Canton of Grisons, Chur, ⁴Health Service for Small Ruminants, Herzogenbuchsee, Switzerland

Objectives: Ovine virulent footrot is a contagious foot disease and occurs in many countries worldwide. The disease is associated with severe pain, affecting animal welfare and causing economic losses. Achieving and keeping a high animal welfare standard and reducing antimicrobial use is of increasing societal relevance. Therefore, the Swiss government decided to study the option of implementing a nationwide footrot control program. The aim of this study was to evaluate the feasibility of elimination of virulent strains (aprV2) of *Dichelobacter nodosus* (*D. nodosus*) from sheep flocks by weekly footbaths.

Materials and Methods: The study was performed in 28 flocks (flock size minimum: 11; maximum: 115; median: 55) with a history of a footrot outbreak between April and December 2015. Initially every sheep was examined for clinical signs of footrot and scored according to the Swiss Health Service for Small Ruminants scoring system (score 0-5) adapted from Egerton and Roberts (1971). A four-feet-pooled cotton swab sample was taken of a maximum of five sheep with clinical signs in order to confirm the infestation with the virulent strain aprV2 of *D. nodosus*. Claws were carefully trimmed. Thereafter, a footbath of the entire flock during 10 minutes using a zinc sulphate (10%) disinfecting solution was performed weekly. Follow-up controls took place in three to four weeks intervals until a successful sanitation was achieved. At controls, every sheep was clinically scored, a four-feet-pooled sample taken and the claws were trimmed if necessary. The DNA was extracted according to

Stäuble et al. (2014). The PCR allowed distinction between the virulent protease aprV2 and the benign protease aprB2 of *D. nodosus*. The flocks were considered successfully sanitised if all sheep were aprV2-negative in the PCR. Follow-up evaluation of all sanitised flocks was performed between March and May 2015.

The correlation between the duration of sanitation and clinical prevalence or flock size, respectively, were analysed with the Spearman correlation in NCSS10. Risk factors for animals being aprV2-positive in the PCR were analysed with a logistic regression model in SAS 9.4.

Results: All 28 farms (100% of the study farms) were successfully sanitised. Seven farms were successfully sanitised after six weeks and the last ones (n=2) after 19 weeks. The number of footbaths (= duration in weeks) was highly correlated with the clinical within-flock prevalence at first visit and the mean score of the flock at first visit. No significant correlations were found between the flock size and the duration of the sanitation or the within flock prevalence at first visit, respectively. Sheep with high scores ≥ 3 were 28 times more likely to be aprV2-positive as compared to sheep with score 0. A number of > 6 footbaths was identified as protective factor.

Conclusions: A complete elimination of aprV2-positive sheep kept segregated from other sheep flocks and ruminants is possibly by weekly footbathing in zinc sulphate (10%), careful removal of loose claw horn and culling of non-responders, without broad scale use of vaccinations or (local or systemic) antibiotics. The duration of the sanitation depends on the initial clinical prevalence of footrot and the mean initial lesion severity score. Further research is warranted in order to optimise the described sanitation program, aiming at increasing farmers' compliance.

SR2-021-007

Estimating the prevalence of ovine *Sarcocystis* spp. from abattoir surveillance of adult slaughter sheep from Tasmania

Clare Phythian ^{1,*}, Peter Windsor ²

¹NMBU, Sandnes, Norway, ²University of Sydney, Sydney, Australia

Objectives: The objectives of this study were firstly, to estimate the prevalence of *Sarcocystis* spp., and secondly, to examine for trends in estimated *Sarcocystis* spp. disease prevalence recorded during routine meat inspection of Tasmania adult slaughter sheep during the last quarter of 2007 and first two quarters of 2013. The aim was to use exploratory data analysis of routine abattoir surveillance data as a means of identifying whether additional producer extension efforts, disease control programmes or specific epidemiological studies examining this cystic parasitic disease in Tasmanian sheep flocks are required.

Materials and Methods: Routine abattoir surveillance data (unpublished) were provided from 1 September 2007 to 30 June 2013 and included date of inspection, local government authority (LGA), abattoir identity (n=9) and the State of inspection (Tasmania, Victoria or South Australia). The dataset provided total count data for the number of sheep killed and, number of sheep inspected, age and sex of each line, and number recorded with macroscopic lesions consistent with *Sarcocystis* spp. in each slaughter line (n = 1960). Data analyses were performed in Microsoft Excel 2007 (Microsoft) and Stata version 13.1 (Statacorp, Texas). Overall surveillance period *Sarcocystis* spp. prevalence (total n sheep recorded with gross *Sarcocystis* lesions divided by total n sheep inspected) and estimated annual *Sarcocystis* spp. prevalence were calculated, noting that 2007 and 2013 were incomplete datasets

for this period. The effect of categorical predictors of State, abattoir and LGA on the dependant variable; recorded line prevalence of *Sarcocystis* spp., were examined in separate fixed-effect linear regression models. Mixed-effects linear regression models were also used to examine the effect of abattoir identity on line prevalence when state was included as a random-effect and abattoir was nested within state. No significant interactions were found. Statistical significance was set as $p < 0.05$.

Results: The dataset represented 355,071 Tasmanian adult slaughter sheep of which 325,325 (91.6%) were inspected across nine abattoirs in three States. Over half of the population (60.0%) was inspected across two abattoirs in Tasmania ($n=195,084$) with 39.8% inspected across 6 abattoirs in Victoria ($n=129,576$) and 0.2% ($n=665$) inspected at a single abattoir in South Australia. Macroscopic lesions of *Sarcocystis* spp. were recorded in a total of 46,381 sheep, equating to an overall surveillance period prevalence of 14.3%. There was variation in the estimated annual disease prevalence, ranging from 0.02% in 2008 to 23.8% in 2011. Tabulation of data by abattoir identity also illustrated clear differences in between-abattoir prevalence of *Sarcocystis* spp. and findings were supported by regression modelling. Regression analysis identified that abattoir identity ($p < 0.001$) was a significant predictor of estimated *Sarcocystis* spp. within-line prevalence in both fixed- and mixed-effects models. Compared to the baseline abattoir for comparison, higher levels of *Sarcocystis* spp. were estimated in lines of sheep inspected at three abattoirs ($p < 0.001$). Inspected lines of sheep of known LGA were also recorded with lower levels of *Sarcocystis* spp. ($p < 0.001$) compared to those of unknown/unrecorded LGA.

Conclusions: Reasons for significant between-abattoir differences in the levels of *Sarcocystis* spp. recorded during routine meat inspection of Tasmanian adult slaughter sheep are currently unknown. This may represent sampling bias, with sub-sets of slaughter sheep going to different abattoirs of varying tiers with different market access, variation in the diagnostic sensitivity of meat inspection across different abattoirs, or differences in the level of registrations, line speeds and inspection and recording speed. Overall, these preliminary findings suggest that further investigation into differing *Sarcocystis* spp. prevalence estimates, is warranted.

Comments: We gratefully acknowledge Animal Health Australia (AHA) for providing the dataset and particularly Lorna Citer for her support. The project was initiated during a World Universities Network (WUN) research mobility exchange programme between the University of Bristol School of Veterinary Science and University of Sydney Faculty of Veterinary Science and was hosted by the Bruce Jackson and Rowena Bell of the Tasmanian Government Department of Agriculture.

SU-036-001

A new predilection site of *Mycoplasma bovis*: outbreaks of postsurgical infected seromas in beef cattle

Linde Gille ^{1,*}, Paola Pilo ², Bonnie R. Valgaeren ¹, Laura Van Driessche ¹, Hans Van Loo ³, Michèle Bodmer ⁴, Sibylle Bürki ², Filip Boyen ⁵, Freddy Haesebrouck ⁵, Piet Deprez ¹, Bart Pardon ¹

¹Internal Medicine and Clinical Biology of Large Animals, Faculty of Veterinary Medicine - Ghent university, Ghent, Belgium, ²Department of Infectious Diseases and Pathobiology, Institute of Veterinary Bacteriology, Bern, Switzerland, ³Animal Health Service Flanders, Torhout, Belgium, ⁴Department for Clinical Veterinary Medicine, Clinic for Ruminants, Bern, Switzerland, ⁵Department of Bacteriology, Pathology and Avian Diseases, Faculty of Veterinary Medicine - Ghent University, Ghent, Belgium

Objectives: In 2014-2015, several Belgian Blue (BB) beef farms in the northwestern region of Belgium reported non-responsive fever, chronic weight loss and seroma formation after caesarean section (CS) in their cows and heifers combined with high mortality. The objective of the present study was to describe involvement of *Mycoplasma bovis* in these outbreaks.

Materials and Methods: All animals included in this study were adult BB cows that recently underwent CS, originating from 3 different farms (farm 1-3) of the same veterinary practice. All animals were examined clinically and with ultrasound. Samples were taken of seroma's and other affected organs and plated on Columbia blood agar (CBA) plates supplemented with 5% sheep blood and on a modified pleuropneumonia-like organism (PPLO) agar plate (DIFCOTM, BD, NJ), incubated at 35°C in an atmosphere enriched with 5% CO₂. Incubation was 48h for CBA plates, and 7 days for PPLO. Bacterial isolates were subsequently identified to the species level with standard biochemical methods. Presumptive *M. bovis* identification was based on the typical fried-egg colony appearance on modified PPLO agar and the presence of lipase activity as tested on medium containing tween-80. After mycoplasma species confirmation by realtime PCR targeting the *uvrC* gene of filter-elongated isolates, strain typing was performed by insertion sequence (IS) elements profiling (Southern blotting) on 6 *M. bovis* isolates, from three cows of two farms.

Results: In farm 1, 4 affected cows could be sampled. Three cows arrived November 2014 (cow 1-3). They had been sick for 2-6 weeks and had been treated with various antibiotics. Two cows (cow 1&2) were euthanized for welfare reasons. These animals were emaciated, with presence of large abscesses (pus filled) and seromas (clear fluid filled) throughout the abdomen. They both had mastitis on four quarters and arthritis on multiple joints. Culture of joint and udder was positive for *M. bovis* in both cases. Abscess fluid of one cow was cultured and contained *M. bovis* and *Aspergillus fumigatus* (different abscesses). Cow 3 appeared normal on the first ultrasound, but did have a *M. bovis* mastitis. She developed two separate seroma's in the following weeks, that both contained pure culture of *M. bovis*. The seromas were drained, and after extensive treatment she could return to the farm. A fourth cow from the same farm arrived in April, with arthritis, mastitis and multiple seromas on ultrasound as well. Again *M. bovis* was isolated in pure culture out of an abscess. Two different herds (herd 2 and 3) reported the same pathologies in June, with again isolation of *M. bovis* from seromas.

IS elements typing showed an identical *M. bovis* strain in animals from herds 1 and 3 (cows 4 and 6, respectively). In herd 1 the isolates from cow 3 (November) and cow 4 (April) were very similar, especially when using ISMbov1 IS elements, but not identical. Within one animal the same strain could be isolated from the udder, joints and the seromas (cows 4 and 6).

Conclusions: In contrast to humans, to the author's knowledge involvement of *Mycoplasma* spp. in wound infections has not been reported in animals. Most likely *M. bovis* spread from a chronic site of infection (mastitis/arthritis) to the surgical wound, possibly aided by physiological immunosuppression in late gestation. The present report underscores the poor prognosis in these cases and the facility by which a single clone can cause similar problems in neighboring farms.

SU-036-002

Toe necrosis, risk factors and a practical surgical intervention to a save cow's life.

Menno Holzhauer ^{1,*}

¹Ruminant Health, GD Animal Health, Deventer, Netherlands

Objectives: Toe necrosis (TN) is a very serious claw-horn affection of especially the tip of the claw whereby the protective horn capsule is no longer present and direct contact between the sensitive pedal bone and surrounding (floor) is possible and present. More than 25 cows were surgically intervened and the results were evaluated based on the presence or absence of lameness

Materials and Methods: Twenty-five cows were diagnosed by MH for the presence of TN and if present a decision to remove the intervention was discussed with the dairy farmer. Data about breed, parity and stage of lactation were collected and the affected claw (front vs hind and medial vs lateral) were registered. After application of ligature around the metacarpus or the metatarsus 10 ml lidocaine or a comparable alternative was injected and after some minutes the surgical removal was performed just behind the necrotic part of the bone. The wound was covered with tetracycline spray and a pressure bandage, which was changed after 4 days and 7 days and completely removed after day 10. Antibiotics were not applied parenterally, a block was placed at the other claw at the same leg

Results: All the 25 cows included in this study were reintroduced in the regular housing situation at 10 days after the intervention, while no bandage was present and the cows were still walking on a block beneath the other claw at the same leg. Very clear was the absence of any lameness almost directly after the removal of the necrotic part. Completely covering of the wound was seen 4 months after intervention (gap was closed), better production and fertility was estimated the size of the claw increased to an almost normal size

Conclusions: In the Netherlands very good experience with resection/removal of the tip of the claw (pedal bone) was gathered with the help of good local anaesthesia. It is simple, takes 10-20 min., the lameness disappears completely and the cow functions normal again (for years) after 10 days bandage. A very simple and practical solution for a very painful situation.

Comments: Nowadays we pay more attention to a good pain management to minimise the pain of the patient and to optimize normal food intake to guarantee better recovery with a minimal loss of milk production.

SU-036-003

Conservative and Surgical Treatment in 36 Ruminants with Limb FracturesAntonio Carlos L. Câmara ^{1,*}Larissa R. Andrade ¹Julio Rafael M. Pereira ¹Marcel B. D. Passos ¹Suyan B. Campos ¹José Renato J. Borges ¹¹Hospital Escola de Grandes Animais da Granja do Torto, Universidade de Brasília, Brasília, Brazil

Objectives: Fractures are encountered on a regular basis in large animal practice. Decision between treatment and euthanasia depends on the economic or genetic value of the animal, the cost of the treatment and the prognosis associated with the particular fracture. Treatment choices vary between stall rest, external coaptation, external fixation and open reduction with internal fixation, depending on the type of fracture and the bone involved. The aim of the present study was to report the main locations of limb fractures in 36 ruminants and to determine the efficiency of the treatment choices.

Materials and Methods: A retrospective study in ruminants with limb fractures attended in two Brazilian Veterinary Teaching Hospitals was performed. Fifteen sheep, twelve cattle and nine goats were included. Conservative treatment (CT) with full limb casts (FLC) or FLC with modified Thomas splint were the method of choice in ruminants with distal fractures and isolate cases of humerus, radio and tibia fractures. In cases of proximal or exposed distal fractures, the ruminants were treated surgically (external fixation, intramedullar pins or plats and screws). In three cases of exposed fractures with extensive bone necrosis and soft tissue damage, limb amputation was the treatment choice.

Results: The higher frequency of fractures involved the metacarpal or metatarsal (n=16; 44.4%) followed by fractures of the tibia (n=10; 27.8%), radius (n=5; 13.9%), femur (n=3; 8.3%) and isolated cases of medial phalanx and humerus fractures (2.8% each). Twenty one ruminants were treated conservatively and achieved a success rate of 95.4% (20/21). Surgical treatment was performed in 12 ruminants and achieved a recovery rate of 100%. Three ruminants were euthanized by owners request. Overall recovery rate reached 91.7% (33/36). Complications included dropped fetlock in the contralateral limb (2/36), osteomyelitis (2/36), cast sores (8/36) and muscle atrophy (36/36). Normal biomechanical limb movement and muscle strength was reestablished in six weeks at the most.

Conclusions: Our results confirms that ruminants are excellent orthopedic patients because of great bone healing properties, limb immobilization tolerance and rare contralateral limb disorders. Use of a Thomas splint and FLC combination is appropriate for fractures distal to the elbow or stifle as observed by our results proving its efficiency in reducing fractures of metacarpal, metatarsal, tibia, humerus, and radio in the treated ruminants. Internal or external skeletal fixation should be considered an option in the treatment of metacarpal, metatarsal, tibial and femoral fractures in ruminants, especially in low body weight animals.

SA-030-001

Technical Feasibility and Experimental Development of Sand Recycling Options for Dairy Cattle Bedding

Jonathan M. E. Statham ^{1,*}, Judith C. H. Dix ², Neil Gray ², Lynsay Blake ³

¹RAFT Solutions Ltd, Ripon, ²School of Civil Engineering and Geoscience, ³Institute for Sustainability, University of Newcastle, Newcastle, United Kingdom

Objectives: Sand is considered the 'gold standard' product for dairy cow bedding in the UK, due to its comfort, absorbency and inorganic nature which inhibits pathogen growth. However, decreasing availability of sand and increasing financial pressure on farm is forcing other considerations such as Recycled Manure Solids (RMS) - more controversial with regards safety and pathogen growth.

Aims:

- 1) Characterise cattle bedding sand (physical, chemical, biological) before and after use
- 2) Compare characteristics of sand to other cattle bedding types
- 3) Review current literature on bedding use /recycling
- 4) Assess recycling efficiency of 6 cattle bedding treatments

Materials and Methods: This investigation was carried out using grab samples of pre-use and used sand bedding material from one farm in North Yorkshire with good practice and well managed sand bedding and pre-use Recycled Manure Solids (RMS) from another farm to characterise the material based on chemical (Carbon, Nitrogen, Phosphorous, Calorific value), physical (qualitative analysis of material structure) and biological characteristics (using baseline respiration, substrate induced respiration, and biogas production potential). Bedding samples were then treated at lab scale with processes which could potentially be implemented in the field i.e. dry heat treated (550°C), single autoclaved (125°C for 18 minutes), double autoclaved (using the principle of tyndallisation, 125°C for 18 minutes times two with 24 hours between treatments), or washed (replicating movement of water in a roller and brush type slurry separator), or with a combination of washing and single autoclaving (as outlined above). Following the processing of the samples, characterisation re-occurred with the exception of calorific value as the pre-use, used and RMS samples produced calorific values all below detectable limits. A complimentary basic pathogen analysis was also carried out on the pre-use, in-use, processed and RMS samples

Results: Pre-use and used sand were physically, chemically and biologically distinct. Sand structure was fine to medium grained, sub-rounded homogenous silicate of grain size of (100 – 500 µm). After use approximately 80% of the material was as pre-use, with the addition of organic matter collections of 1-5cm diameter. Significantly higher levels of moisture, organic content, respiration potential and pathogen counts were noted in post-use sand when compared to pre-use sand.

RMS (alternative bedding option), displayed distinct qualitative and quantitative qualities to pre-use and post-use sand. The structure of RMS was very different from sand, appearing as very low density, fibrous heterogeneous material, with fibres of up to 3cm in length. RMS chemical and biological characteristics (before use) (i.e. moisture content, organic content, respiration potential and pathogen counts), were far higher than either clean bedding sand or post-use bedding sand. RMS was exempt from treatment methods, as the standard treatment is to dry this material and reuse.

Post-treatment of sand bedding: no significant differences in the physical properties of the sand based on microscopy based inspection. Dry heat treatment of the sand at 550°C in an oven reduced respiration potential to below that of clean, pre-use sand and samples contained no mastitis causing pathogens after treatment. Washing used sand significantly lowered respiration potential and pathogen colonies relative to the

post-use levels. Autoclaving was deemed to be least successful as a treatment method, and enhanced biological activity.

Conclusions: For pathogen removal and returning sand to its original state of comfort and absorbency, autoclaving was ineffective.

Washing samples reduced sand to pathogen levels of pre-use sand; when combined with autoclaving, the number of mastitis causing pathogens counted increased: combining washing with autoclaving has no advantage.

The most effective treatment method was to dry heat treat the sand at 550°C. This returned sand to its original physical properties and completely removed mastitis causing pathogens from the sand.

Future work is required to optimise conditions for treatment options and evaluate cost benefit and societal acceptance.

SA-030-002

The growing importance of Farm Animal Para professionals (Vet Techs) as part of a Veterinary Led team in the UK.

Jon Reader ¹, Mark Burnell ¹

¹Synergy Farm Health, Evershot, United Kingdom

Objectives: The report on veterinary expertise in food animal production by Philip Lowe in 2009 argued that the veterinary profession needed to draw closer to its customers. It recommended that an area to be explored was 'the appropriate development of the roles of veterinary technicians'. Farmers are also increasingly under pressure to reduce costs including veterinary spend.

This presentation/poster outlines how a large animal practice in the South of England has grown this part of their business, the roles that can be performed, the role of the veterinary surgeon in managing the business and the potential for a new income stream.

Materials and Methods: A large veterinary practice in the South West of England servicing 45,000 dairy cows with 28 vets is described. The para professional team is described in detail and the varied roles that they perform throughout the business. The management structure and quality control and audit of these staff is discussed as well as HR considerations. The recruitment and continued professional development of these staff is discussed and the challenges of staff retention. The various financial models for such a service are discussed including the main one used in this business.

Results: 15 veterinary technicians (paraprofessionals) are employed by the practice. These include 7 qualified foot trimmers, 2 clinical veterinary technicians, 2 dairy hygienists, 3 SQPs (suitably qualified persons) and a laboratory technician.

Some of the services on offer include Cattle Foot trimming, mobility scoring, general animal handling, freeze branding, sampling, assisting vets with routine procedures such as debudding, vaccination, specialist fertility work (including ET), laboratory diagnostics, milking machine troubleshooting, client training, advice on worming strategies and trial work.

Conclusions: The provision of this service to the farm animal sector is vital to the ongoing supply of veterinary services on farm. The authors believe that retaining these skills under a veterinary led team allow a joined up approach on farm while facilitating quality data collection as well as maintaining animal health and welfare. The authors highlight that they see the Veterinary Technician/Para professional as potential the future for the farm animal veterinary sector.

SA-030-003

Impact Of Routine Hormone Treatments For The Reproductive Management Of Dairy Herds On Methane Emissions And Reproductive Efficiency

Simon Archer ^{1,*} Christopher Hudson ¹ Martin Green ¹¹School of Veterinary Medicine and Science, University of Nottingham, Sutton Bonington, United Kingdom

Objectives: The aim of this study was to evaluate the magnitude and between herd variation of changes in methane emissions and economic efficiency associated with 3 simple hormonal interventions to manage breeding in early lactation.

Materials and Methods: Data for 10,000 herds of 200 cows were simulated. Probability of conception was predicted daily from the start of the study (at a calving) for each cow, up to day 300 of lactation. Four scenarios of differing first insemination management were simulated for each herd, using the same theoretical cows: A baseline scenario based on breeding from observed oestrous events only, synchronisation of oestrous for fixed time first insemination using 2 methods, and a regime using prostaglandin treatments followed by first insemination to observed oestrous events. Cows that did not conceive to first insemination were re-inseminated following detection of oestrous. For cows that conceived, gestation length was 280 days with cessation of milking 60 days before calving. Those cows not pregnant after 300 days of lactation were culled and replaced by a heifer. Daily milk yield was calculated for 730 days from the start of the study for each cow. Change in mean reproductive and economic outputs were summarised for each herd following each intervention. For each scenario, methane emissions were determined by daily forage dry matter intake, forage quality, and cow replacement risk. Linear regression was used to summarise relationships between input and output variables.

Results: In some circumstances improvement in reproductive efficiency using the programmes investigated was associated with reduced cost and methane emissions compared to reliance on detection of oestrus alone. Efficiency of oestrus detection and the time to commencement of breeding after calving influenced variability of changes in cost and methane emissions. For an average UK herd there was a saving of at least £50 per cow and a 3.6% reduction in methane emissions per L of milk when timing of first insemination was pre-set. The global warming potential of this change is equivalent to that from 2 cars, a family home, or 21 barrels of oil.

Conclusions: Use of hormonal interventions in the reproductive management of dairy herds can be controversial. In some circumstances for every litre of milk produced, both economic and environmental benefits through reduced methane emissions occurred. However, this was not universal across all farm scenarios simulated. It is therefore important that hormonal interventions can be prioritised; for circumstances associated with a demonstrable benefit to society in terms of food security and sustainability, in addition to economic efficiency for the farmer.

SA-030-004

Preliminary results of an investigation of methods of establishing deep cubicle beds of recycled manure solids for dairy cows in the UK

David Black ^{1,2,*} Katharine Leach ³ Andrew Bradley ³ Ian Ohnstad⁵Martin Green ⁴¹Paragon Veterinary Group, ²XLVets UK Ltd, Carlisle, ³QMMS, Wells, ⁴School of Veterinary Medicine, University of Nottingham, Loughborough, ⁵The Dairy Group, Taunton, United Kingdom

Objectives: Deep beds of recycled manure solids (RMS) can provide comfortable beds for cows. However, farmers have reported that the bedding may not dry out optimally, and heating may occur, if a large amount is initially put into cubicles. Such conditions could influence microbial growth and adversely affect udder health. It has been suggested that building up the beds gradually may be preferable. This experiment was designed to test whether building beds gradually was associated with drier bedding and less heating. In addition the impact of the presence of cows during the bed building phase was assessed.

Materials and Methods: The study was conducted at Sewborwens Farm, Newton Rigg, Penrith, Cumbria, CA11 0AG, UK. Sixteen cubicles were used for the trial, four being allocated to each of four treatments:

- 1) Rapid Fill with Cows (RC): Beds filled to capacity with RMS on day 1 with cows having access.
- 2) Rapid Fill no Cows (RNC): Beds filled to capacity with RMS on day one with no cows having access.
- 3) Slow Fill with Cows (SC): Beds filled with shallow layers of RMS daily, aiming to reach full capacity on Day 7 with cows having access.
- 4) Slow Fill no Cows (SNC): Beds filled with shallow layers of RMS daily, aiming to reach full capacity on Day 7 with no cows having access.

The trial was replicated twice in two different sets of cubicles in the same shed.

On days one to seven, the depth of bedding and the temperature at 2.5 cm depth were recorded in each cubicle, and a sample (approximately 100g) of bedding was collected from the top 2.5 cm of the bed for determination of dry matter (DM). On day 29, the total depth of bedding was recorded and temperatures were measured and samples were collected for DM analysis at 2.5 cm depth intervals. Temperature, relative humidity and wind speed in the shed were recorded by data loggers throughout the study.

Data from the two replicates were analysed separately, to compare bed parameters between the four treatments, using non-parametric tests in view of the wide variation evident in the data.

Results: Replicate 1 demonstrated that bedding in rapid filled cubicles with cows reached the highest temperatures during the week of establishment (17 oC vs 11-12 oC for slow filled). DM content was lowest in slow filled with cows (36% v 38-39%, $p < 0.05$). After four weeks the slow built beds were significantly cooler at 5 cm depth and tended to have a higher DM content at Day 29 than rapidly filled beds, but the effect of occupation by cows was no longer significant. In Replicate 2, under warmer environmental conditions, both rapid fill treatments reached higher median temperatures (19-24 oC) than slow fill treatments (14 oC) ($p < 0.05$) during week one, but the presence of cows did not have a significant influence during this time. In contrast to Replicate 1, DM % was higher with slow filling than with rapid filling during the building phase (39-42% v 36-38%, $p < 0.05$). After four weeks the bed temperature with cows present was higher than without, but the only significant difference between individual treatments was a lower temperature in SNC compared with other treatments ($p < 0.05$).

Conclusions: Rapid building of beds elevated temperatures of bedding in the building phase, and the effect appeared to persist for four weeks. Temperature was affected more by speed of fill than by the presence of cows. The effect of building speed on DM content at the surface during the first week and four weeks later was inconsistent. Dry matter content of the surface material appears to be influenced by factors in addition to

the speed of bed building which may include the presence of cows. There appears to be a complex interaction between environmental conditions, including temperature and relative humidity, and the temperature and DM of RMS bedding.

Comments: This has been submitted under Udder Health as it will be related to the paper submitted by Andrew Bradley et al, but you may decide it is more appropriate in another section?

SA-030-005

Carbon footprint of sheep production systems in the Mediterranean climate zone of Chile: Simulation model.

Paula Toro Mujica ^{1,*}, Claudio Aguilar ¹, Raúl Vera ¹, Einar Vargas-Bello-Perez ¹

¹Departamento de Ciencias Animales. Facultad de Agronomía e Ingeniería Forestal, Pontificia Universidad Católica de Chile, Santiago, Chile

Objectives: A simulation model developed previously was modified with the aim of estimating the carbon footprint of extensive sheep production systems in the Mediterranean climate zone of Chile, with the purpose of determining the influence of operating variables and the pattern of rainfall on carbon footprint and productivity. Together, the relative importance of ecosystem service "carbon sequestration" (grassland and soil) on the carbon footprint of sheep extensive systems was quantified.

Materials and Methods: Main pastoral resource for sheep production in the region correspond to the natural prairie basically the called Mediterranean annual pasture. Other grazing species observed in the area correspond to subterranean clover, falaris and oats. On the other hand, the use of cereal stubble is a necessary and common practice during the summer months. The sale of the lambs, in these systems is usually performed during the months of September to December, with animals from three to four months of age and weighing between 28-35 kg., generally unweaned. To assess the carbon footprint Cradle to farm-gate methodology proposed by FAO (2010) was used, which implies that emissions of greenhouse gases were assessed for all processes involved until that the lambs leave the farm. The production of carbon per kilogram of live weight of lamb was the functional unit used to assess the carbon footprint. The estimation of GHG emissions based on the equations of Tier 2 proposed by IPCC (2006) was realized. Three typical farms present in the zone were simulated. Three pattern of precipitation (dry, normal and wet) were used for to determinate the grassland growth. Three supplementation levels, five levels of stocking rate variation and grassland with and without fertilization were simulated. Factorial experiments were used to evaluate the effect of changes in stocking rate, supplementation level of sheep and fertilization of natural pastures (and weaning) about the carbon footprint (CO₂-eq/kg live weight of lamb). The simulations were realized with and without the valuation of ecosystem services.

Results: All factors studied had a significant effect on the carbon footprint, weight of lambs, weight of sheep and grassland availability. Interactions of second, third and fourth orders were observed. Average carbon footprint obtained was 14.8 CO₂-eq/kgLW. The incorporation of carbon sequestration did decrease this value to 2 CO₂-eq/kgLW. Increasing stocking rate caused an increase in the carbon footprint, but this trend was reversed with the addition of carbon sequestration. The weights of lambs and ewes, as well as the final grassland availability decreased to the extent that increased stocking rate. The effect of supplementation

during the period studied was the smallest on the studied variables. Fertilization grassland (and weaning) elevated the carbon footprint due to the decrease in the weight of lambs and emissions from fertilizers used, but increased the weight of ewes. The years with lower rainfall showed the highest carbon footprints and caused significant decreases in the values of the other variables studied.

Conclusions: The model allows predicting the effect of management changes and precipitation pattern on the carbon footprint and productive variables. Incorporating some of the ecosystem services provided by sheep production systems modifies the effect of the studied factors on carbon footprint. An integral assessing of sheep production systems for assessing their impact on the production of greenhouse gases is necessary. The model developed is a first approximation.

TP1-045-001

Comparison of Two Macrolides in the Control of BRD in Calf Ranch CattleNorman Stewart ^{1,*}¹Technical Services, Merck Animal Health, De Soto, United States

Objectives: The purpose of this study was to determine the health performance of calf ranch cattle at high risk for developing bovine respiratory disease (BRD) after the administration of two different macrolides for the control of respiratory disease.

Materials and Methods: Holstein heifers (165 - 240 lbs). predicted to be at high-risk for BRD were utilized in this trial. BRD incidence, with no previous use of an injectable BRD control agent, was 20%.

On the same day, all animals were individually weighed, their temperature taken, BVD PI tested, randomly allocated antibiotic given after they left their hutch at +/- 60 d of age and prior to entering their randomly assigned pen.

Treatment groups were Tildipirosin: 4 mg/kg (1.0 ml/cwt), s.c., 1 x with a 3 day post metaphylactic interval (PMI) or Tulathromycin: 2.5 mg/kg (1.1 ml/cwt), s.c., 1 x with a 3 day PMI.

Animals were placed in equal sized pens (max 55/pen, 2 paired pens per replicate, 22 replicates on test). 1,030 animals received Tildipirosin and 1,029 received Tulathromycin at enrollment. Workers then observed the animals daily for clinical BRD signs. They were blinded to treatment and trained to uniformly score clinical signs. BVD PI animals were removed from the study.

When an animal was sick after 3 day PMI, 40 mg/kg florfenicol, 2.2 mg/kg flunixin meglumine, 6 cc/ cwt., s.c., 1 x with a 4 day post treatment interval (PTI) was injected. Clinical signs included nasal and ocular discharges, respiratory rate and character, presence and character of cough, demeanor (depression), and gauntness. Based on any one of these clinical signs, animals were treated for BRD. Animals with one or more signs were assigned a depression and respiratory score (0=normal, 1=mild, 2=moderate, 3=severe).

All animals were weighed off test the same day, +/- 42 d on test,

Results: There was a statistical difference ($p=0.032$) with regards to morbidity following the administration of the respective treatment groups' antibiotic for the control of BRD. Ninety-five animals or 8.46% (95/1,030) of the animals treated with Tildipirosin broke with BRD compared to 128 animals or 11.43% (128/1,029) of the animals treated with Tulathromycin.

There were no statistically significant differences ($p < 0.05$) between the two treatment groups with regards to respiratory and depression scores, treatment success rates following treatment with 40 mg/kg florfenicol: 2.2 mg/kg flunixin meglumine, mortality, chronics, relapses and body temperatures.

Conclusions: This large field study demonstrated that treatment with Tildipirosin was superior to Tulathromycin in reducing Bovine Respiratory Disease morbidity with both antibiotics having a 3 day PMI, when used to control BRD in calves.

TP1-045-002

Efficacy of flunixin meglumine pour-on administration in a tissue cage model of inflammationOlivier Roy ¹René Fournier ²Julien Thiry ²Philippe Brianceau ³Siddhartha Torres ^{3,*}¹CEBIPHAR, Fondettes, ²MSD Santé Animale, Beaucouzé, France, ³Merck Animal Health, Madison, United States

Objectives: The objective of this study was to evaluate in cattle the effect of flunixin meglumine applied topically in reducing PGE2 concentration in exudates after induction of subcutis inflammation using a tissue cage model.

Materials and Methods: Six healthy not-lactating dairy cows (514 ± 42 kg) and six healthy grass calves (369 ± 49 kg) were included in the study and randomly assigned to two treatment sequences. Sterile hollow perforated polyethylene balls were surgically embedded in the subcutis at four distinct sites per animal three weeks prior to D0. On D0 and D14, an aseptic inflammation of the subcutis was induced by injecting in three balls per animal 0.5 ml of a 2% carrageenan solution. Carrageenan challenge was immediately followed by the topical treatment on the dorsal midline area: NaCl or flunixin meglumine (3.33 mg flunixin meglumine / kg body weight). Exudate was collected prior to challenge and 2, 4, 8, 12, 24, 36, and 48 hours after. Cages were emptied after each collection. PGE2 concentrations were measured in exudate using a validated liquid chromatography coupled with mass spectrometry method. Each animal received the two items as treatment sequentially on D0 and D14 according to group assignment.

Results: In NaCl-treated animals, PGE2 concentration levels displayed a sharp increase, peaked 8 hours after challenge, and gradually decreased over time (PGE2 concentration levels were still elevated 48 hours after challenge). In flunixin meglumine treated animals, PGE2 peak occurred later (12 hours after challenge) and was strongly reduced compared to that in NaCl treated animals: PGE2 concentrations were consistently lower than those measured after NaCl administration. Percent of inhibition was close to or over 90% at the peaks of PGE2 concentrations (8 and 12 hours after challenge) after flunixin meglumine treatment, and inhibition lasted until the end of the animal phase. The log ratio of concentrations for the two treatment groups are significantly different (linear mixed model, p values ≤ 0.05) at hours 8, 12, 24, 36 and 48, but are not significantly different at hours 2 and 4.

Conclusions: This study shows that flunixin meglumine applied topically inhibits carrageenan-induced subcutis inflammation in cattle. Anti-inflammatory effects occurred as soon as 2 hours and lasted at least for 48 hours post-administration.

TP1-045-003

Early detection of bovine respiratory disease and immediate treatment with flunixin help to reduce the use of antibiotics in beef calvesC. C. Gelfert ^{1,*}C. Ströbel ²C. Beisl ³E. Thesing ⁴D. Lange ¹¹Intervet Deutschland GMBH, Unterschleissheim, ²Ströbel Christina_Beratungsdienst Rindermast, Ilshofen, ³Gassner Franz & Beisl Josef_Tierärztl. Gemeinschaftspraxis, Frontenhausen, ⁴Intervet Deutschland GMBH, Unterschleissheim, Germany

Objectives: The use of antibiotics (AB) is monitored in Germany since midyear 2014 and beef farmers are forced to implement new strategies to reduce the use of AB. New tools to detect fever in calves provide the opportunity to detect bovine respiratory disease (BRD) in an early stage and to treat these animals with an NSAID alone. In the early stage of BRD, viruses are the main pathogen, thus an antibiotic may not be necessary. Then, treatment with an NSAID alone may be sufficient to both inhibit inflammation and control the infection.

The hypothesis of our study was that an early treatment of BRD in calves with flunixin will reduce the use of AB by 33%.

Materials and Methods: The study was performed on 2 beef farms in southern Germany. New arrived calves (n= 40 per farm) were clinically examined and vaccinated intranasally against BRSV and PI3V. A probe (fevertag®) was installed in one ear to measure constantly the calves body temperature. A fever tag alarms by a red flushing light if body temperature is constantly > 39.7°C for 6 h. Fever alarms were monitored for 8 weeks. During this time each fever alarm was reported and allocated randomly to two treatment groups. A repeated alarm on the same calf was counted as a new case if the time interval between two alarms exceeded 7 days. On both farms antibiotics were fed orally for the 1st 14 days, a general method in Germany for new arrived calves on beef farms.

In a case of an alarm (=d 1), rectal body temperature confirmed fever (>39.7°C). In case of fever they were randomly assigned to 2 treatment groups and treated the same day. Calves assigned to the control treatment (n=37) received one injection of florfenicol and flunixin. Calves assigned to the study treatment (n=43) were treated once with flunixin as pour on (3.3mg/kg). All calves were clinically examined on d 2. If fever or clinical signs of BRD were observed further treatment was performed with florfenicol. Calves were finally examined for clinical disease and fever on d 6 to close a case.

Descriptive parameters were used to describe the effects of the different treatments. Frequency of additional treatment in the study group (and 95% CI) was calculated. The sign-test was performed to test our hypothesis.

Results: During the study period, 80 cases of fever alarm were monitored, 24 calves showed two fever periods. Mean body temperature at first treatment was 40.2°C. Besides a slight increased lacrimation in a few calves, no other clinical signs were visible. Appetite was not reduced in all but two calves.

Of the 80 cases, 37 cases were treated with florfenicol and flunixin and all but three calves did not require further treatment. 43 cases were allocated to the study treatment and treated with flunixin only. In 29 cases (67.4%, 95% CI [50.5%; 80.9%]) no further treatment till day 6 was necessary. According to the sign test, the reduction in the use of AB was significantly above the 33% of our hypothesis (P=0.0315).

Conclusions: In case of early BRD detection, these results show that early treatment with flunixin reduced the use of AB in fattening calves by 67%. This seems to be an effective strategy for beef farmers to comply with the new German legislation to reduce antibiotic usage. Further studies should show whether these tools of early detection also help to minimize metaphylactic treatments with antibiotics in beef cattle farming.

TP1-045-004

Chemical residues in dairy cattle following use of organic therapies for mastitis

Ronald Baynes^{1,*}, Keena Mullen², Sharon Mason³, Kevin Anderson¹, Steve Washburn²

¹Population Health and Pathobiology, North Carolina State University College of Vet Med, ²Animal Science, North Carolina State University, Raleigh, ³Biological Sciences, Campbell University, Buies Creek, United States

Objectives: Many consumers in the United States are demanding that food animals be raised without using antibiotics as evidenced by the increase in certified organic food production. There is great incentive to assess alternatives to antibiotics. Many plant essential oils, extracted from plant material, have been historically used as antibacterial and anti-inflammatory agents. This presentation will focus on the pharmacokinetics of two chemicals in many antibacterial plant essential oils, thymol and carvacrol, that are major components of several products used on organic dairy farms in the U.S.

Materials and Methods: An intramammary (IMM) product (Phyto-Mast, CowMaster LLC, Narvon, PA) containing both carvacrol and thymol or a topical udder product (Uddersol, Ralco Animal Health, Marshall, MN) which contained only carvacrol was administered at 1X or 2X the recommended dose to healthy mid-lactation Jersey cross dairy cows (n = 10) in a randomized design. Plasma and milk samples were collected periodically for up to 5 days after the last dose. Tissue samples were also collected to assess residue depletion in liver, kidney, muscle and fat. All samples were analyzed by headspace solid-phase microextraction coupled with gas chromatography-mass spectrometry (SPME-GC/MS/MS). All milk, plasma, and tissue analytical methods were developed and validated in our laboratory. The limit of quantification (LOQ) was 0.0005 µg/ml for all matrices. Pharmacokinetic noncompartmental modeling was performed using Phoenix® (Certara, St. Louis, MO, USA) to estimate plasma and milk pharmacokinetic parameters for each chemical.

Results: IMM administration of Phyto-Mast resulted in thymol and carvacrol early peak plasma concentrations (< 0.02 ppm average) at about 25 minutes that declined rapidly to below limit of quantification (LOQ) within 12 hours. The apparent plasma half-life of thymol and carvacrol were 1.69 hr and 1.70 hrs, respectively. Peak milk concentrations were at 4 hrs for most cattle and ranged from 0.5 – 9.0 ppm thymol and 0.5 – 12 ppm carvacrol, but declined to below LOQ within 12 hours.

Topical Uddersol resulted in peak plasma carvacrol concentrations (< 0.002 ppm average) at 1-4 hours with levels below LOQ after 12 hours. Comparisons of plasma area under the curve (AUC) values suggested a 2-fold greater relative bioavailability of carvacrol from Phyto-Mast than from Uddersol. As anticipated, carvacrol concentrations in milk were also greater with Phyto-Mast than Uddersol as peak carvacrol levels from the latter were always less than 0.35 ppm.

Preliminary tissue concentrations for thymol and carvacrol from IMM Phyto-Mast were relatively low in liver (0.0068 ppm and 0.0051 ppm), kidney (0.010 ppm and 0.0066 ppm) and muscle (0.0058 ppm and 0.0066 ppm), respectively. Topical Uddersol resulted in low levels of carvacrol in kidneys (0.0118 ppm), fat (0.0072 ppm), muscle (0.0062 ppm), and liver (0.0027 ppm). All tissue concentrations were at the reported peaks 24 hours after slaughter and had dropped below the LOQ by 96 hours.

Conclusions: We demonstrated that chemical components in IMM or topical mastitis therapies can be detected in milk for several hours and in tissues for just a few days after the last dose. Thymol and carvacrol were cleared from the milk within 24 hrs but persisted longer in various organs and edible tissues. These estimates are based on a limited dataset

and further analyses are required. With the growth of the organic dairy industry in the United States and global concerns over antibiotic use in livestock, it is important to evaluate these and similar alternatives to antibiotics to ensure food safety.

TP1-045-005

Sodium iodide inactivates *Manheimia hemolytica* and *Bibersteinia trehalosi* in vitro.

Meera Heller ^{1,*}, Brian VanderLey ², Kristin Clothier ³, Benjamin Newcomer ⁴

¹Veterinary Medicine and Epidemiology, University of California Davis, Davis, ²Veterinary Medicine and Surgery, University of Missouri, Columbia, ³California Animal Health and Food Safety Laboratories, University of California Davis, Davis, ⁴Veterinary Pathobiology, Auburn University, Auburn, United States

Objectives: Bovine respiratory disease is an important cause of economic loss in the cattle industry. The airway epithelium has several innate defense mechanisms to protect the health of bovine lungs; one of these is lactoperoxidases (LPO) and hydrogen peroxide (H₂O₂) which react with excreted halide ions to form hypohalous acids on the epithelial surface. The objective of this study was to determine if two important bovine bacterial respiratory pathogens, *Manheimia hemolytica* and *Bibersteinia trehalosi* (formerly *M. hemolytica* biotype T), are susceptible to inactivation by the LPO/H₂O₂/halide system that is present in bovine airways.

Materials and Methods: Clinical isolates from bovine pneumonia cases presented to the diagnostic lab for post-mortem examination were used in this study. Isolates were identified via traditional biochemical testing and confirmed via MALDI-TOF. Experiments were carried out on three different strains of each bacteria. The susceptibility of these pathogens to inactivation by hypiodous acid was determined by generating HOI in vitro using LPO, sodium iodide (NaI) and H₂O₂. Concentrations of NaI from 50 µM to 500 µM were tested, and controls were run in parallel. Subsamples were removed prior to addition of H₂O₂ (catalyst) and at 5 and 30 minutes. Bacterial killing was assessed via standard plate counts. Experiments on each strain were performed in duplicate, on three separate occasions.

Results: Results of previous studies have showed this system to be effective at inactivating human respiratory syncytial virus and adenovirus. In this study we found that the complete reaction mixture (LPO, H₂O₂, NaI) killed both of our bacterial pathogens, *M. hemolytica* and *B. trehalosi*, at all concentrations of NaI tested (50-500 µM). Bacteria was killed by 5 minutes after initiation of the reaction. A surprising finding was that NaI alone at higher concentrations (above 250 µM) inactivated both pathogens immediately in vitro.

Conclusions: NaI and its product, hypiodous acid, show exciting promise as a preventative strategy for bovine respiratory disease. In human studies, orally administered NaI results in elevated levels of iodide in respiratory secretions. Introducing high levels of iodide in airway secretions in cattle at times of peak stress and susceptibility to respiratory disease may prove a valuable preventative strategy for respiratory disease, which may also help to reduce antimicrobial use in food producing animals.

TP1-045-006

Prevention of Neonatal umbilical infections in Holstein calves through accelerated desiccation of the umbilical remnant utilizing a novel therapy

Julie Gard ^{1,*}, Debra R. Taylor ¹, Sue Duran ¹, Soren Rodning ², Terri Hathcock ³, Megan Schnuelle ¹, William Justus ⁴, Christy Bratcher ², Fred DeGraves ⁵, Brad Fields ⁶

¹Clinical Sciences, Auburn University College of Veterinary Medicine, ²Animal Science, Auburn University, ³Microbiology, Auburn University College of Veterinary Medicine, Auburn, Alabama, ⁴Animal Science, Harding University, Searcy, Arkansas, ⁵Agriculture, Western Kentucky University, Bowling Green, KY, ⁶Agriculture and Industries, Alabama State, Montgomery, AL, United States

Objectives: Reduction of navel infections through appropriate management including navel dipping is beneficial to the calf and the producer and is reported to decrease navel infection rates from 20-28% to 5-14%. Obviously, navel dipping is of great importance but obtaining tincture of iodine has become problematic. It has become necessary to develop other products that can be utilized to dry the umbilicus and assist in the prevention of navel infections. Hence, the objective of this study was to evaluate an alternative to 7% tincture of iodine, Super7+™ Navel Dip.

Materials and Methods: A total of a 100 neonatal Holstein heifers were utilized in this study. Fifty calves were dipped with treatment A, (Super7+™ Navel Dip) immediately following calving and 50 were dipped with treatment B, (7% tincture of iodine). The umbilicus and the umbilical remnant of all calves were evaluated 48 hours following dipping and at least a 1 cm segment of umbilical remnant was removed and placed in a labeled airtight container. All samples were analyzed within 6 hours of sampling and in 12 hour increments until the samples contained less than 10% moisture. A serum sample was collected from each calf within 48 hours of birth and tested for total protein, immunoglobulins (IgG) and specific gravity. The workers dipping the calves and the technicians analyzing the samples were blinded to the treatment.

Results: Of the remnants undergoing treatment A, 88% and 100% were desiccated within 48 hours and 60 hours, respectively. Of the umbilical remnants undergoing treatment B, 58% and 100% were desiccated by 48 hours and 60 hours, respectively. There was a strong association between treatment A and drying at 48 hours. (P = 0.0008, Mantel-Haenzel Chi-Square). The odds of drying out at 48 hours were 5.31 times higher with treatment A compared to treatment B. There was no clinical evidence of umbilical infection in any of the calves utilized in this study. The total protein, IgG and specific gravity were analyzed from all calves (mixed linear models) and were determined to not be significantly different between treatments (P = 0.415, P = 0.439, and P = 0.300, respectively).

Conclusions: Treatment A (Super7+™ Navel Dip) appears to be superior to tincture of iodine in its ability to more quickly desiccate the umbilical remnant. Hence, Treatment A (Super7+™ Navel Dip) appears to function competently as a navel dip and is a viable alternative to 7% tincture of iodine.

TP2-046-001

Treatment of bovine respiratory disease in juvenile calves with a single administration of a combination of florfenicol plus flunixin meglumine

Siddhartha Torres¹, Julien Thiry¹,* Vincent de Haas¹

¹Merck Animal Health, Madison, United States

Objectives: Whether Bovine Respiratory Disease (BRD) causing factor is physical, environmental, or infectious, a sequence of events occurs resulting in inflammation and ultimately activation of the innate and adaptive immune systems. It is advisable that NSAID and anti-infective agents are used concurrently to treat BRD. The present study intended to confirm the efficacy and the safety of the florfenicol-flunixin combination formulation for the treatment of BRD in juvenile calves less than 6 weeks of age in comparison to an approved positive control, florfenicol, that represented a negative control in regards to flunixin meglumine.

Materials and Methods: A total of 210 calves of less than 6 weeks of age, originating from France, Germany and Spain, and showing severe signs of respiratory disease (depression score ≥ 2 , respiratory score ≥ 2 and rectal temperature $\geq 40.3^{\circ}\text{C}$), were enrolled and randomly assigned to treatment. Each animal was randomly assigned to treatment with either the test product, 300 mg/ml florfenicol plus 16.5 mg/ml flunixin formulation (Resflor®; 40mg/kg florfenicol and 2.2mg/kg flunixin; 2ml/15kg; MSD Animal Health), or the control product, 300 mg/ml florfenicol formulation (Nufloor®; 40mg/kg; 2ml/15kg; MSD Animal Health). Both products were administered once subcutaneously in the neck on day 0. To avoid observation bias and to preserve masking, treatments were dispensed and administered by individuals not involved in the clinical assessment. All animals were observed daily for depression, respiratory character and rectal temperature for 10 days post-treatment. From day 4 to day 10, animals with a depression score ≥ 1 or a respiratory score ≥ 2 that had a rectal temperature $\geq 40.0^{\circ}\text{C}$ were classified as treatment failures and removed from the study. The dosing sites was evaluated and any adverse effects were recorded. All animals underwent nasopharyngeal swabbing for bacterial culture, identification and determination of florfenicol sensitivity.

Results: The predominant respiratory pathogens were *Pasteurella multocida*, *Mycoplasma bovis*, *Mannheimia haemolytica* and *Histophilus somni*. All isolates were found susceptible to florfenicol.

In both groups, rectal temperature significantly dropped and clinical index (depression and respiratory signs) significantly improved after treatment. Specifically, for the change in rectal temperature from pre-treatment to 6 hours post-treatment, the florfenicol-flunixin formulation was found significantly superior to florfenicol ($p < 0.0001$). Moreover, the florfenicol-flunixin formulation alleviated the clinical signs of disease more rapidly, and was demonstrated non-inferior to florfenicol on days 4 and 10 success rates.

Neither florfenicol-flunixin formulation nor florfenicol had a negative influence on the health status including appetite and faecal consistency, confirming that both products are safe.

Conclusions: Prompt treatment of sick calves with a NSAID (e.g. flunixin) in conjunction with a broad-spectrum antibiotic (e.g. florfenicol) helps reduce fever, control bacterial replication, and reduce the likelihood of lung consolidation. This study demonstrates that the single administration of Resflor® can be used successfully to treat juvenile veal calves with respiratory disease.

TP2-046-002

Evaluation Of An Alternative Therapy For Infectious Bovine Keratoconjunctivitis

Julie A. Gard¹,* Debra R. Taylor¹, Rachel Maloney¹, Megan Schnuelle

¹Sue Duran¹, Philip Moore¹, Will Justus¹, Paul Walz², Ricardo Stockler¹, Soren Rodning³, Fred DeGraves⁴, Edzard van Santen⁵, Misty Edmondson¹, Annette O'Conner⁶, Amanda Windham⁷

¹Clinical Sciences, ²Pathobiology, Auburn University College of Veterinary Medicine, ³Animal Science, Auburn University, Auburn, ⁴Agriculture, Western Kentucky University, Bowling Green, ⁵Crop, Soil and Environmental Sciences, Auburn University, Auburn, ⁶Diagnostic and Production Animal Medicine, Iowa State University, Ames, ⁷Animal Science, Auburn University, Auburn, Alabama, United States

Objectives: Infectious bovine keratoconjunctivitis (IBK), commonly called "pink eye", is a painful condition affecting beef and dairy cattle worldwide. The bacterium, *Moraxella bovis* is known to be responsible for this condition. Antibiotic therapy has been primarily utilized for this condition. However, there is a need to reduce the amount of antibiotics utilized in food animals. Hence, the objective of this research was to evaluate an alternative therapy (Vetericyn Plus™ Pinkeye Spray) to promote healing and aid in the reduction of pain and infection due to experimentally induced IBK.

Materials and Methods: Thirty dairy bull calves having determined to have normal ophthalmic examinations and who were culture negative for *M. bovis* were randomly assigned to three groups for a single eye block randomized blinded challenge study. Calves were housed in pairs according to their respective group in an approved isolation facility. On day zero a 0.6 mm corneal lesion was made on the center of the left corneas of Groups 1 and 2 utilizing n-heptanol. Immediately following lesion formation, 1.0×10^7 of *Moraxella bovis* (strain Epp63-300; origin: NADC) was administered topically to the left central corneas of Groups 1 and 2. The calves in Group 3 (Control group) received topical corneal administration of *M. bovis* to their left eyes but nothing further. Starting on day one, each calf in Group 1 received two mLs of Vetericyn Plus™ Pinkeye Spray topically to each cornea twice daily for 10 days. Additionally, calves in Group 2 each received two mLs of 0.9% Saline topically to each calves' cornea twice daily for 10 days. Each animal was given a pain score twice daily (based on blepharospasm, ocular discharge and tearing). All eyes were cultured on day -7, 0, 1-5, and day 10. Digital images were taken of each eye of each calf from day 0 to day 10 of the study. The lesions were measured daily utilizing Image-J technology. Additionally, serum and plasma samples were drawn from all calves on days 0, 1, 10, 11, and 17 and evaluated for changes in sodium and chloride levels. Statistical evaluation was performed utilizing SAS® and a Kenwood-Roger correction was utilized.

Results: All calves in group 1 and 2 developed lesions in the left eye as determined by fluorescein staining. All calves in group 2 developed lesions consistent with IBK in the left eyes. Calves in group 2 only were determined to be culture positive for *M. bovis* during the study period. Between Days 1 and 2, Group 1 had significantly, $P < 0.05$, decreased pain scores when compared to controls. On average there was a reduction in pain score by 79.1% by day 2 and an 83.7% reduction in pain by day 10 when compared to controls. Group 2 had an average reduction in pain score of 18.3%, and 67.9% by day 2 and by day 10, respectively, when compared to controls. There was no significant difference in sodium and chloride levels in the plasma and serum among all three groups at any of the sampling time points ($P < 0.05$). The days to cure was significantly different between Group 1 and Group 2 ($P = 0.0161$) and there was a significant difference in the treatments when evaluating lesion width and circumference ($P = 0.0147$) and ($P = 0.0375$), respectively.

Conclusions: The results of this study indicates that an alternative therapy (Vetericyn Plus™ Pinkeye Spray) can significantly aid in the reduction of pain, infection and healing time of corneal lesions in calves experimentally infected with *M. bovis*.

TP2-046-003

Altered Plasma Pharmacokinetics of Ceftiofur Hydrochloride in Cows Affected with Severe Clinical Mastitis

Patrick Gorden ^{1,*}, Michael D. Kleinhenz ¹, Larry W. Wulf ¹, Butch KuKanich ³, Chang J. Lee ², Chong Wang ¹, Johann F. Coetzee ^{1,2}

¹Veterinary Diagnostic and Production Animal Medicine, ²Pharmacology Analytical Support Team (PhAST), Iowa State University, Ames, ³Department of Anatomy and Physiology, Kansas State University, Manhattan, United States, ⁴Division of Food and Environmental Sciences, Wonkwang University, Iksan, Korea, Republic of Korea

Objectives: The objective of this study was to compare the plasma pharmacokinetics of ceftiofur hydrochloride between healthy dairy cattle and those afflicted with severe clinical mastitis. Our hypothesis is that cows affected with severe infectious disease will have altered ceftiofur pharmacokinetics relative to healthy cows, necessitating variance in dose regimens and withdrawal periods

Materials and Methods: Eight cows with naturally occurring mastitis and eight clinically healthy cows were treated with 2.2 mg of ceftiofur hydrochloride/kg of body weight once daily for five days via the intramuscular route. Blood was collected at 0, 0.33, 0.67, 1, 1.5, 2, 3, 4, 8, 16, and 24 hours after the first ceftiofur administration and every eight hours thereafter until 120 hours after the final dose. Plasma samples were analyzed for ceftiofur concentrations using liquid chromatography coupled with mass spectrometry. Ceftiofur concentrations are reported as total ceftiofur which includes the parent compound and all metabolites. Single dose and multi-dose non-compartmental pharmacokinetic models were determined for both groups.

Results: With the exception of time 0, ceftiofur was detected at all time points. The disease group had a significantly higher plasma ceftiofur concentration at T=3 h after the first injection and a significantly lower plasma concentration from 40-152 h following the first injection, with the exception of the T=64 h time point. Data following the first injection (Time 0-24 h) were fit to a single dose, non-compartmental pharmacokinetic model. This model indicated that the disease group had a shorter plasma half-life. A multi-dose, non-compartmental model was used to determine steady state pharmacokinetics. Compared to control cows; the disease group had an initially higher peak concentration, a higher volume of distribution and drug clearance rates. The disease group also had a lower area under the curve per dosing interval, steady state concentration maximum, and dose-adjusted peak steady state concentration. All other pharmacokinetic parameters were not different between the two groups.

Conclusions: These data show that significant pharmacokinetic changes occur in diseased animals administered ceftiofur relative to healthy, control animals. These outcomes potentially have public health significance in that: 1) drug efficacy could be lower than expected; 2) there may be an increase in violative drug residues in tissues of cull animals or milk; and 3) this may lead to increases in antimicrobial resistance. Further work examining protein binding, tissue distribution, and tissue depletion of drugs and their influence on residue levels in diseased animals is necessary to more thoroughly characterize this problem.

TP2-046-004

Use of Antibiotics on United States Dairy Operations

Jason Lombard ^{1,*}, Charles Fossler ¹, Ashley Adams ², Christine Kopral ¹

¹USDA:APHIS:VS, Center for Epidemiology and Animal Health, ²Department of Animal Sciences, Colorado State University, Fort Collins, CO, United States

Objectives: Veterinarians are the primary health providers and/or consultants on most U.S. dairy operations. In these roles, veterinarians are usually involved in the selection and use of antibiotics. Preventing drug residues in milk and meat has always been a priority for veterinarians, and guidelines for judicious use of antibiotics are available to dairy practitioners. The use of antibiotics in livestock agriculture is coming under increased scrutiny because of the focus on reducing antibiotic resistance. The objective of this study was to describe the use of antibiotics on dairy operations.

Materials and Methods: The National Animal Health Monitoring System's (NAHMS) Dairy 2014 study was conducted in the nation's top 17 dairy states. These states represented approximately 80% of U.S. dairy operations and 80% of U.S. dairy cows. During March through July 2014, veterinary medical officers or animal health technicians visited 265 dairy operations that had at least 30 cows. Multiple questions from the study's questionnaire focused on antibiotic use during 2013 in the following cattle classes: preweaned, weaned, pregnant, and adult. Statistical software, which accounted for the complex study design, was used to provide estimates reflective of the U.S. population of dairy producers.

Results: Ionophores were fed to weaned heifers on 50.5% of operations and to 62.7% of all weaned heifers. Similarly, 39.3% of operations, representing 46.8% of all pregnant heifers, fed ionophores to pregnant heifers. Cows were fed ionophores on 37.0% of all operations. Treatment with intramammary antibiotics at dryoff was practiced on 88.5% of operations, and overall 93.0% of all cows were dry treated. For dry-cow therapy, third generation cephalosporins were used on 22.3% of dry-treated cows. Diarrhea was the most common disease in preweaned heifers: 21.3% of all heifers were affected with diarrhea, and 15.9% of were treated with antibiotics for diarrhea. The primary antibiotics given for diarrhea were third-generation cephalosporins (28.1% of treated preweaned heifers), trimethoprim/sulfa (19.2%), and aminoglycosides (14.9%). Respiratory disease affected 8.2% of weaned heifers. The primary antibiotics used for respiratory disease were florfenicol (32.2% of treated weaned heifers) and macrolides (29.3%). The percentage of cows treated with antibiotics for common diseases were 20.8% for mastitis, 7.8% for reproductive disease, 3.7% for lameness, 2.7% for respiratory disease and 1.2% for digestive disease. On operations that treated cows with antibiotics, third-generation cephalosporins were used to treat cows for mastitis on 50.8% of operations, lameness on 59.6%, respiratory disease on 78.3% and digestive problems on 61.9% of operations.

Conclusions: Ionophores are frequently used as feed additives on dairy operations, but this class of antibiotics is not listed as 'medically important' by the FDA and, thus, is not affected by the recent FDA guidance documents. Third-generation cephalosporins, trimethoprim/sulfa, and macrolides are all considered critically important for use in humans. However, these drugs are being used in the dairy industry primarily for disease treatment purposes, and relatively few cattle are treated with these drugs.

TP2-046-005

Comparison of tildipirosin and tulathromycin for control of bovine respiratory disease in high-risk beef heifersRiccardo Compiani ¹Stefano Jottini ²Siddhartha Torres ^{3,*}¹Practitioner, ²MSD Animal Health, Milano, Italy, ³Merck Animal Health, Madison, United States

Objectives: The Italian beef system is based on fattening young calves imported from abroad. Cattle are inevitably subject to stressful transport conditions, which last on average 8 to 12 hours. Even under excellent management conditions and administration of well-designed immunization protocols, preventive antimicrobial treatment is often required to reduce morbidity and mortality due to Bovine Respiratory Disease (BRD). The purpose of this study was to evaluate the effectiveness of tildipirosin (TIP) and tulathromycin (TUL) administered to newly received beef heifers at risk to develop BRD for reducing morbidity and mortality under field conditions.

Materials and Methods: A total of 785 Charolais heifers considered to be at high risk of developing undifferentiated BRD were enrolled in the study. Heifers were grouped and randomly allocated in pair to receive either tildipirosin (ZUPREVO® TIP; n=398; at 4 mg/kg) or tulathromycin (DRAXXIN® TUL; n=387; at 2.5 mg/kg). Morbidity due to BRD was defined as animals showing mild to severe depression and/or respiratory signs and having a rectal temperature $\geq 104^{\circ}\text{F}$ (40°C). Animals diagnosed with BRD (first episode) were administered 2 doses of florfenicol at 9.07 mg/ lb (20 mg/ kg) 48 hours apart. Average daily gain (ADG) was also recorded. Data collected at slaughter included cold-carcass weight, dressing percentage, and lung lesions within a subgroup of animals (n = 433; 207 for TIP vs 226 for TUL). Continuous variables were analyzed with Student's t-test. Variables expressed on either a binary or ordinal scale were analyzed using the chi-square test.

Results: BRD morbidity was lower in the TIP group compared to heifers in the TUL group (6.8% TIP vs 20.9% TUL; $P < 0.01$). At the end of the 125-day feeding period, heifers in the TIP group were heavier ($P < 0.01$) and had 0.15 lb (0.07 kg) greater ADG ($P < 0.01$). Carcasses of TIP group animals tended to be heavier at slaughter ($P = 0.06$), but there was no difference in dressing percentage. Nearly 70.7% of first-pulled animals did not have lung lesions at slaughter, therefore, metaphylaxis supplemented by effective therapeutic treatment was an effective strategy under the conditions of this study.

Conclusions: Under the conditions of this study of high-risk heifers, treatment at arrival with tildipirosin reduced morbidity compared to treatment with tulathromycin. Lower BRD morbidity favorably influenced ADG. Health history before arrival at the feedyard is an essential element of information for accurate BRD risk assessment of beef cattle

TU1-017-001

Development and Evaluation of an Enzyme-Linked Immunosorbent Assay (ELISA) for the Detection of Bovine Tuberculosis

Ralph Lausterer ^{1,*}, Roland Hardegger ¹, Patrick Mossi ¹, Alex J. Raeber ¹¹R&D, Thermo Fisher Scientific, 8952 Schlieren, Switzerland

Objectives: Cell-mediated immune (CMI) responses are the principal and earliest immune responses to develop after infection with *Mycobacterium bovis*, the causative agent of bovine tuberculosis. In contrast, antibody responses develop considerably later than CMI responses but from a practical perspective serological based test assays are useful tools to complement the diagnostic portfolio for bTb testing because of the stability of antibodies during sample transport, storage and handling. Here the development of an ELISA for the detection of bovine tuberculosis is described – the PrioCHECK™ Tuberculosis Complex Ab

Materials and Methods: The PrioCHECK™ Tuberculosis Complex Ab is an indirect ELISA test to detect antibodies directed against *Mycobacterium bovis* antigen which is coated in wells of a microtiter plate. Serum samples are incubated in the wells of the plate and *Mycobacterium bovis* specific antibodies are captured by the immobilized antigen on the plate followed by detection with a peroxidase (POD) labeled anti-bovine IgG. The PrioCHECK™ Tuberculosis Complex Ab can be used for single sample analysis as well as for high throughput testing applications.

Results: A total of 835 samples were tested with the prototype PrioCHECK™ Tuberculosis Complex Ab (541 positive and 294 negative samples). 50 samples derived from an Irish and 204 samples from UK negative herds, defined on historical records of > 5 years bTb free history based on skin test and BOVIGAM™ negative test results. Furthermore 200 negative samples from the USA and 56 negative samples from Switzerland were tested. 11 samples provided by the APHA were confirmed as bTb positive reactors (skin test and BOVIGAM™ positive test results). In addition 38 positive Irish, 100 positive US and another set of 138 UK positive samples were analysed. The ELISA cut-off was set at 15% positivity based on receiver operating characteristic (ROC) analysis. The measured diagnostic sensitivity was about 66 % (95 % CI, 60.3 - 71.4), the specificity about 98 % (95 % CI, 96.2 – 99.2).

Cross-reactivity was determined with samples from *M. kansasii*, *M. avium* and *M. avium* paratuberculosis. 46 *M. avium* paratuberculosis positive samples from Ireland, the Netherlands and the USA were measured. In addition 8 *M. kansasii* and 8 *M. avium* positive samples from the USA were determined. Overall, none of the 62 samples analysed showed reactivity in the ELISA.

Conclusions: The PrioCHECK™ Tuberculosis Complex Ab is a suitable and reliable tool for the detection of bovine tuberculosis. It shows no cross-reactivity towards other mycobacteria. The determined sensitivity of 66 % and specificity of 98 % makes it an ideal tool to complement the diagnostic portfolio for the detection of bovine tuberculosis.

TU1-017-002

The effect of seasonality on ranging behaviour in Irish badgers.

Teresa MacWhite ^{1,*}, Peter K. Maher ¹, Enda M. Mullen ², David J. Kelly ³⁴Margaret Good ¹, Nicola M. Marples ^{3,4}

¹Department of Agriculture, Food and the Marine, Department of Agriculture, Food and the Marine, Kildare Street, Dublin ², ²National Parks and Wildlife Service, Department of Arts, Heritage and the Gaeltacht, Wicklow Mountains National Park, Laragh, Co. Wicklow, ³Department of Zoology, School of Natural Sciences, ⁴Trinity Centre for Biodiversity Research, School of Natural Sciences, Trinity College Dublin, Dublin ², Ireland

Objectives: The ranging behaviour of badgers and their movements through the environment are of direct importance to the transmission of tuberculosis (TB) infection both between individual badgers and their social groups, and also between badgers and the cattle on the farms through which they travel. The objective of this study was to investigate the year-round ranging behaviour patterns of male and female European badgers in a medium density population in Co. Wicklow, Ireland. The effect of sex and age of the badgers and seasonality, in terms of temperature, rainfall and photoperiod, was also evaluated.

Materials and Methods: Over a three-year period, from May 2010 to May 2013, 19 male and 19 female badgers were fitted with Global Positioning System (GPS) tracking collars (Tellus Light collar by Followit, Sweden). The collars were programmed to take either four or eight GPS readings per night according to the season. When eight GPS readings or attempted readings had been recorded in the collar's memory, the collar sent a text message to Followit in Sweden, who then relayed the positional data to the authors by e-mail. The resulting data was converted to Irish grid and used to calculate home range estimates. Data analysis was conducted using the statistical environment "R" (version 2.14.1). Home range estimation was done using the minimum convex polygon (MCP) method and the local convex hull (LoCoH) incorporating the 'adaptive sphere-of-influence' version (a-LoCoH). Generalised linear mixed models (GLMMs) were used to describe changes in ranging behaviour. Factors such as sex, age, month, temperature, and rainfall were examined and all possible models were generated and ranked using Akaike Information Criteria for small samples (AICc scores).

Results: 33928 GPS readings were received from the 38 badgers. The maximum home range recorded for a male was 724 hectares (ha) in April 2013 and 323 ha for a female in June 2010. The home ranges varied greatly in size between individuals (e.g. between 576 ha and 35 ha in the same month). The mean home range size for all males was largest in April 2013 at 287 ha, while the mean for females was largest in June 2010 at 166 ha. A seasonal cycle in range size was clear with summer ranges being significantly larger than winter ranges. Male and female badgers had similar range sizes up to their second year. Males aged 3-5 years had the largest home ranges. Males reduced their winter ranging less than the females and the females entered winter lethargy more than the males did.

Conclusions: This study showed that male badgers over three years had the largest home ranges, whereas females and younger badgers of both sexes had smaller ranges. Males were flexible regarding winter lethargy and maintained a full home range through the winter in some years. These results are important for understanding the dynamics of TB transmission both within badger populations and between badgers and cattle. In addition, our findings may aid the optimisation of vaccine delivery programmes by allowing the targeting of specific age and sex cohorts.

TU1-017-003

Temporal association between badger presence and herd bovine tuberculosis (bTB) risk in County Monaghan, Ireland

Paul White^{1,*}, S. W. Martin², Guy McGrath¹, Mart C. De Jong³, James J. O'Keeffe⁴, Francisco Olea-Popelka⁵, Simon J. More¹, Andrew Byrne⁶, Klaas Frankena⁷

¹UCD CVERA, Dublin, Ireland, ²Department of Population Medicine, Ontario Veterinary College, Ontario, Canada, ³Quantitative Veterinary Epidemiology, Wageningen University, Wageningen, Netherlands, ⁴Dept of Agriculture, Dublin, Ireland, ⁵College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, United States, ⁶Agri-food and Biosciences Institute, Belfast, United Kingdom, ⁷Wageningen University, Wageningen, Netherlands

Objectives: In Ireland, badgers are culled in response to herd breakdowns of bovine tuberculosis (bTB), where implicated following an epidemiological investigation of the 'index herd' episode. Our goal was to quantify relative temporal trends in bTB risk before and after culling of badgers from the land of surrounding herds (those with 33% of land area within 500m of an affected sett) in county Monaghan during 2004-2011.

Materials and Methods: To describe herd 'exposure' in relation to badger presence we assumed that a culled badger had been present around the sett for the previous 6 months (exposure period). After badger removal, we assumed that surrounding herds would experience a period of decreased badger presence ('post-exposure period'). We further assumed that this decreased badger presence might affect the outcome of a herds next bTB test, provided that appropriate time-lags were observed (eg to account for test latency).

The first Cox survival Models (Model A) tested the null hypothesis that there was no decline in herd bTB hazards in the 'post-removal' period (i.e. the next herd test ≤ 15 months later). Model B, tested the hypothesis of no difference in bTB hazard before badger removal compared with all other times. The outcome was a herd experiencing a bTB episode. In both A & B, we controlled for herd size, enterprise type, count of previous bTB episodes, being within a former experimental removal area, and being an index herd.

In A, we estimated the earliest date when the next herd test could be counted as 'post-badger removal'. We accounted for possible test latency by including a range of time-lags. (ie with 'badger removal date' delayed by 0, 1, 2 and 3 months). Models were compared using Akaiques' Information Criteria (AIC); the lowest AIC lag model was considered "best". The resulting time-lag was used to define the end of the exposure period for B.

Results: Over the period 2004-2011, 860 setts were approved for capture in relation to 112 index herds. A total of 1,102 badgers were captured at 354 of these setts on 748 occasions. In relation to the 860 setts, 1,155 surrounding herds were selected as the study population (25% of herds in the county). Following sett approval, 178 bTB episodes occurred in 159 of the surrounding herds. 140 herds experienced 1 and 19 experienced 2 bTB episodes.

Model A

A negative relationship between herd bTB risk and increasing months to the next test was observed in all four versions of Model A, as measured by the time-varying covariate for the competing models of timelags 0, 1, 2 and 3 months. A time-lag of 2 months (AIC = 2,287) was selected as the lowest value, (i.e. the model with most plausible time-lag). In Model A, decreasing hazards were observed from 2 months after badger removal until the next test (equivalent to a 17% decrease in hazard per month; $p = 0.003$).

Model B

Prior to badger removal, the hazard ratio was significantly increased (H.R. = 1.82; $p = 0.001$), compared to other times.

Conclusions: The finding of decreasing hazards for bovine TB in cattle following badger removal, and increased hazards for herd bTB during the period of assumed badger presence adds to the already compelling evidence of an association between bovine TB in the two species. Since the study population represents only a subset of herds within 1 county in Ireland, caution should be applied in generalising these results more widely.

TU1-017-004

Does spill-over of bovine tuberculosis from badgers occur at cattle yards or troughs, or by direct contact ?

Paddy Sleeman^{1,*}, Declan O'Mahony²

¹School of Biological, Earth and Environmental Sciences, University College, Cork, Ireland, ²Agri-Food and Biosciences Institute, Agri-Food and Biosciences Institute, Belfast, United Kingdom

Objectives: Spill-over of bovine tuberculosis from badgers to cattle is important, but where and how this spill over occurs, remains unclear. Spotting such spill-over events might be achieved if we knew more about this, they may be by badgers visiting cattle yards or troughs, or by direct contact at pasture. It is a subject of some controversy, in an already controversial, and difficult topic. Over recent decades, badgers have been detected in cattle yards, and at troughs, in Ireland both north and south, and in southern England. The objective here is to review data generated in Ireland recently, and compare that with findings from England.

Materials and Methods: Methods used in Ireland to study this included field observations, rainfall recording to see if it influenced results, sand bands, cameras, radio-tracking, proximity collars, GSM collars and in addition, winter surveys of 200, 100 beef and 100 dairy, randomly selected yards. The latter surveys were for badger signs, especially tracks in mud, at a time of year when cattle were indoors, in County Cork. Work in Northern Ireland was in County Down. Both areas had TB blackspots. In England there was more emphasis on selected farms, as well as marking badgers, radio-tracking, video surveillance, and rainfall recording.

Results: Very few signs of badgers were detected in yards, and it appears that badger tend to avoid them in Ireland. The accuracy of the ability to find badger tracks in winter was tested using two teams one of which realised badgers and one of which checked for badger tracks the next day. Badgers have also been detected troughs in both parts of Ireland. In England there was more emphasis on selected farms, as well as marking badgers, radio-tracking, video surveillance, and rainfall recording. One hundred and thirty nine visits by twenty six badgers were reported in one study in England.

Conclusions: Despite use of modern techniques spill-over is not yet understood. Considerable variation by season and month, herd/group size and climate variables as well as at an individual level were recorded in Northern Ireland. The ecology of both badger and cattle Ireland and Britain a different. This may explain why the results between the two countries, are conflicting, and difficult to compare.

TU2-018-001

Replacing reactive culling of badgers by badger vaccination: part of the end-game of the eradication of bovine tuberculosis in the Republic of Ireland

James J. O’Keeffe ^{1,*} Wayne S. Martin ² Andrew Byrne ³ Paul White ⁴ and Robert Doyle, Martin Fitzgerald, Martin Hayes, Diarmuid Lynch, Peter Monaghan, Michael O’Brien,

¹Ruminant Animal Health, Department of Agriculture, Food and the Marine, Republic of Ireland, Dublin ², Ireland, ²Department of Population Medicine, Ontario Veterinary College, Guelph, Canada, ³Veterinary Sciences Division, Agri-Food and Biosciences Institute, Belfast, United Kingdom, ⁴Ruminant Animal Health Division, Department of Agriculture, Food and the Marine, Dublin ², Ireland

Objectives: The objective of this work is to ascertain if intra-muscular (IM) vaccination of badgers, with BCG, is not inferior to area-wide targeted badger culling in maintaining a reduced herd-level risk of bovine tuberculosis (bTB) in the Republic of Ireland (ROI). Badgers (*Meles meles*) are an important reservoir of *M. bovis* in ROI. The current bTB eradication program involves an annual test/slaughter program in cattle plus localized targeted badger culls where epidemiological investigations link badgers to bTB breakdowns. The cull area in ROI covers circa 28% of agricultural land with circa 6,500 badgers removed annually.

Materials and Methods: Six counties in ROI were selected for the study. Suitable areas (at least 150 km² with road, water, or mountains as boundaries) within each county were deemed vaccination areas; the remaining area within the counties receive continued culling of badgers. Vaccination/release of badgers starting in County Longford in 2011. The project was rolled out in stages with all sites becoming fully operational by 2014. Testing data from cattle in these six counties will be analysed/evaluated. Our primary outcome of interest are herd breakdowns with 3 or more standard SICCT reactors during an episode (an episode is the interval a herd is prohibited from trading). Badgers in the areas designated for vaccination with BCG, will be captured, marked, vaccinated and released. Outside the designated areas in the participating counties badgers will be culled as per the national program. In the study counties, it is unlikely that vaccination will be superior to continued culling hence our interest is whether or not vaccination will lead to a bTB risk, in cattle herds, that is not inferior to that produced by the current culling program. Vaccination need just be not more than a defined amount worse (called the inferiority margin and represented here by δ : Δ), than continued culling in terms of bTB risk in cattle herds. We denote the risk of this in herds in the current (or culling) program area as p_c and in the area with badger vaccination is denoted as p_v . Our null hypothesis is a one-sided comparison $H_0: p_v - p_c \geq \Delta > 0$ where $p_v - p_c$ is a small value that has little practical importance.

Results: Formal analysis of the results from the 6 counties sites will not take place until the end of 2017 and will cover the period 2014-2017. Results from one county, Longford, will be presented for the period 2011-2014. The outcome variable of primary interest is the proportion bTB breakdowns in herds resulting in the identification of 3 or more standard interpretation reactors. In county Longford, since vaccination commenced in 2011, larger breakdowns have remained below 1% of episodes overall and the risk of larger breakdowns has not been any higher in the vaccination zones compared to the rest of the county. Overall, nationally, there has been a circa 50% reduction in episodes of bTB in cattle herds since 2001 and these data will be presented in terms of the categories of breakdowns as defined by the numbers of standard reactors identified per episode in the study counties. Because badgers are a protected species, culling in the ROI is carried out under licences issued by the Heritage Dept. Targeted culling programs are undertaken that maintaining badger populations at reduced densities in areas where bTB is endemic in cattle and by association in badgers also. The current

capturing program commenced in 2003 and the area under capture has grown since then and now covers a cumulative area that is circa 28% of all agricultural land. How these culling areas evolved in the 6 study counties will be outlined, as will the trends in bTB herd breakdowns over the interval up to 2014.

Conclusions: This trial will end in Dec 2017 when a decision on whether using BCG vaccination in endemic TB areas in the ROI will be taken then. Vaccinating badgers, if not inferior to continued culling and therefore a suitable part-substitute for the continued culling of badgers which is currently carried out annually, will result in fewer badgers culled. A strategy that includes vaccination of badgers as a part-substitute for culling will be sustainable in the longer term as lower cull rates will not threaten the longer-term viability of ROI badgers. Such a strategy will contribute to the national goal of achieving TB-Free status by 2030.

TU2-018-002

The impact of local weather on European badger (*Meles meles*) capture success: implications for bovine tuberculosis management

Laura Martin ^{1,2} James O’Keeffe ^{3,4} Andrew Byrne ⁵ Francisco Olea-Popelka ¹

¹Department of Clinical Sciences, ²Graduate Degree Program in Ecology, Colorado State University, Fort Collins, United States, ³Department of Agriculture, Food and the Marine, ⁴Centre for Veterinary Epidemiology and Risk Analysis, University College Dublin, Dublin, Ireland, ⁵Veterinary Sciences Division, Agri-food and Biosciences Institute, Belfast, United Kingdom

Objectives: Bovine tuberculosis (bTB) affects livestock and wildlife around the world. Badgers (*Meles meles*) are an important wildlife reservoir in Ireland and Britain, which complicates disease eradication efforts. In the Republic of Ireland, badgers have been managed through culling to control bTB, but vaccination using the intramuscular *Bacillus Calmette-Guérin* (BCG) vaccine is becoming the new goal. However, for vaccination to be effective, badger trapping success must be high to deliver vaccines to a large proportion of badgers in a given population (coverage). In this study, we examined the effect of local weather on badger capture success.

Materials and Methods: We compiled data from 1,985 badger captures during 2010-2013 as part of a bovine TB badger vaccine trial in County Kilkenny, Ireland. Trapping using stopped restraints and cage traps occurred at active setts (dens) for a period of 8 nights, with traps checked daily. At the start of a trap session, field staff assigned an activity score to the setts, based on a scale of 0-5. For each trap night, field staff collected data on minimum and maximum air temperature and assigned a precipitation score from 1-6, ranging from dry to snow. We compared Poisson, zero-inflated Poisson, negative binomial, and zero-inflated negative binomial models to evaluate factors affecting badgers capture numbers.

Results: In our preliminary analysis, we found that badger captures were significantly higher in drizzle (25%, $p = 0.01$), rain (22%, $p = 0.02$), and heavy rain (32%, $p = 0.006$), and significantly lower in snow (72%, $p = 0.03$) compared to dry weather. Badger captures were significantly higher (69%, $p < 0.001$) at setts with activity scores of 4 as compared to setts with activity scores of 3. There was a quadratic relationship between temperature and badger captures. We are currently continuing to analyze additional data to account for variation trapping effort (traps laid per sett).

Conclusions: Our results provide valuable information for prioritizing trapping based on local weather conditions. Increasing capture success will increase vaccination rates, which will increase protection against the development of bovine TB amongst badgers. Effectively vaccinating badgers will be a crucial aspect and a key step toward the goal of eradication of bovine TB in Ireland.

TU2-018-003

The role of tuberculin assays on naturally infected cattle in the Irish bovine tuberculosis eradication programme.

Anthony Duignan¹*Margaret Good¹¹Department of Agriculture Food and Marine, Ireland, Dublin, Ireland

Objectives: Periodic assays in naturally infected tuberculous cattle, as recommended by the WHO Technical report series 384, fulfils a critical function as part of overall quality control of the Irish bovine tuberculosis eradication programme in order to assure optimal diagnostic surveillance. This poster gives an account of the procedures and outlines the role of tuberculin PPD assays carried out on naturally infected cattle in the quality control on the Irish Bovine Eradication Programme.

Materials and Methods: Cattle are injected at 4 sites on either side of the neck. Injections are rotated sequentially through each of the eight possible neck sites in each of 24 cattle using the Latin square design so as to minimise any statistical bias due to variations in skin sensitivities at the different skin sites. The injection sites are clipped and the skin-fold thickness at each injection site is measured using a manual calliper with 1 mm graduations at 0 hours. The tuberculin PPDs are injected intradermally using McLintock syringes. Skin fold thickness are re-measured at each site at 72 hours.

Results: The results are analysed using standard statistical methods for parallel-line assays according to Finney (1), using the GLM procedure within the statistical software package, SAS(SAS Institute Inc., 2003). The outcome measure is the increase in skinfold thickness after 72 hours and all models included a term for animal to account for repeated measures on the same animal. The concentration term is transformed using logs and included in the model as a linear term. Separate slopes are assessed for each tuberculin by testing the interaction term (log_concentration x tuberculin) within the model. This is the test for parallel slopes. If this interaction term is not significant then the relative potency can be calculated as the difference in average skin increase between the test and standard tuberculin divided by the slope (the increase in mean reaction per unit increase in log dose). Site and Side of the injection are included in the final model if significant. The 95% confidence limits for the relative potency are calculated according to Fieller's method (Finney, 1978)

Conclusions: Successive cattle assays have validated the results of guinea pig assays as batches found to have potencies of 30,000 [66-150%] I.U. per ml by guinea pig assay also exceeded this potency when assayed in cattle. Cattle assays are considered essential to ensure that EU requirements for tuberculin potencies are achieved and periodic assays in naturally infected tuberculous cattle remains necessary as part of overall quality control of the Irish bovine tuberculosis eradication programme.

TU2-018-004

Where and when are badgers (*Meles meles*) bovine tuberculosis positive? Data from culled populations across the Republic of Ireland

Andrew Byrne^{1,2}*Kevin Kenny³James O'Keeffe¹Ursula Fogarty⁴Simon More¹Guy McGrath¹Marian Teeling³Wayne Martin⁵Ian Dohoo⁶

¹Centre for Veterinary Epidemiology and Risk Analysis, University College Dublin, Dublin, Ireland, ²Veterinary Science Division, Agri-food and Biosciences Institute, Belfast, United Kingdom, ³Central Veterinary Research Laboratory, Dublin, ⁴Irish Equine Centre, Kildare, Ireland, ⁵University of Guelph, Guelph, ⁶University of Prince Edward Island, Charlottetown, Canada

Objectives: European badgers (*Meles meles*) are an important wildlife host of bovine tuberculosis (bTB; *Mycobacterium bovis*), and have been implicated in the epidemiology of bTB in cattle herds in Ireland and the United Kingdom (UK). The objectives of the study were to determine the spatial and temporal trends of bTB in badgers in Ireland, while also investigating associations between the characteristics of badgers and local cattle TB prevalence.

Materials and Methods: The bTB status of 4900 badgers culled (2009-2012) as part of a targeted policy of reducing badger density in areas where cattle herds experienced bTB "breakdowns" was determined using well established *M. bovis* culture techniques. We applied multivariable Generalised Estimating Equation (GEE) modelling and Geographic Information System (GIS) analysis to assess the spatial and temporal trends in badger apparent prevalence using these data. Risk factors assessed included badger characteristics (age class, gender, parity), sett (burrow) characteristics (size, distance to other setts), and local area cattle bTB prevalence.

Results: We found significant variation in badger prevalence in both space and time. There was a trend in apparent prevalence towards westerly regions having higher risk than easterly regions of the country. Over time there was a significant linear reduction in bTB risk. There was a clustering effect within the dataset, with animals caught within the same sett having a higher bTB status correlation than between setts. Furthermore, badgers caught at setts that were closer to other "infected" setts were at higher risk of testing positive for bTB. Badger infection risk was associated with local area cattle herd prevalence (within 1km of the badger sett) during the year when the badger was captured. Non-parous female badgers were found to have lower risk than parous-female or male badgers.

Conclusions: Over the study period the apparent prevalence of bTB in badgers in culled areas decreased significantly. However, there was significant geographic variation in prevalence across Ireland. We found a significant association between badger risk and local area cattle prevalence (≤ 1 km of the badger sett). This observational study adds evidence to the association between badgers and cattle concerning the epidemiology of bTB in Ireland. However, our data cannot determine the direction of infection. At an animal level, we found that the pregnancy status of female badgers significantly impacted on their likelihood of being culture positive for bTB.

TU2-018-005

The avoidance of farmyards by European badgers *Meles meles* in a medium density population.

Enda Mullen ^{1,*}, Teresa MacWhite ², Peter Maher ³, David Kelly ⁴, Nicola Marples ⁴, Margaret Good ³

¹National Parks and Wildlife Service, Department of Arts, Heritage and Gaeltacht, Laragh, ²Department of Agriculture, Wicklow, ³Department of Agriculture, ⁴Department of Zoology, School of Natural Sciences, Trinity College, Dublin, Ireland

Objectives: The objective of this study was to see if badgers used farmyards as often as would be expected from their availability within the landscape. It also investigated the influences of farmyard type, season, gender and social group membership on the likelihood of a badger entering a farmyard.

Materials and Methods: This Irish study is the first to have looked at the use of a variety of farmyard types by badgers. Over a three-year period 40 free-ranging badgers from a medium-density population in Co. Wicklow were fitted with GPS collars. Locational data received from the collars were used to create home ranges for each badger in each season. A Farm Bias Index was developed using paired T tests with a Holm correction. GLMMs were used to examine the effects of the season, gender and social group variables.

Results: We found that badgers in our study area avoided all types of farmyards. This avoidance was significant in nine of the 12 seasons. Badgers particularly avoided those farmyards where cattle were present. If badgers did enter a farmyard it was more likely to be an equestrian yard or a disused farmyard than a cattle yard.

We found no impact of seasonality, social group membership or badger gender on this behaviour. Half the badgers in the study visited at least one yard over the three years. There was some evidence of individual preferences on the part of the badgers.

Conclusions: While our results differ from the findings of studies carried out in high-density badger populations in Great Britain, it is not possible to distinguish those density effects from differences in farming practices in GB. It is likely that badger behaviour and ecology as well as cattle stocking density and biosecurity must be taken into account when designing measures to control the transmission of this disease. The results of this study strengthen the growing body of evidence that transmission of TB between badgers and cattle is less likely to be through direct contact than through fomites or other indirect means.

Comments: *Mycobacterium bovis* (TB) in cattle is a zoonotic disease with far-reaching effects throughout Europe but especially in Great Britain and on the island of Ireland. Wildlife reservoirs, in particular the European badger *Meles meles*, continue to play an important role in the transmission of the disease, although the pathways of transmission are still poorly understood. The badger is an opportunistic feeder that takes advantage of seasonally abundant foods, such as fruits and soil invertebrates. Badgers might therefore be expected to enter farmyards to exploit grain stores or feed concentrates. This would bring them into close proximity with livestock present in those yards, potentially increasing the opportunity of disease transmission. Increasing our knowledge of the interactions between badgers and cattle in a variety of ecological situations is essential to assist in proactive and general control of TB in both species.

TU2-018-006

A preliminary assessment of oral vaccine bait uptake by wild badgers in Ireland

David Kelly ^{1,*}, Margaret Good ²

¹Department of Zoology, Trinity College Dublin, ²Department of Agriculture, Food and the Marine, Agriculture House, Kildare Street, Dublin, Ireland

Objectives: Culling remains a controversial method of maintaining low badger populations in areas where wildlife reservoirs of *Mycobacterium bovis* persist. Current long-term plans aim to replace culling with oral and/or parenteral vaccination of badgers. We investigated the uptake of vaccine-free baits by wild badgers across Ireland to assess suitable levels of bait density deployment and pre-feeding (prior to live vaccine bait deployment) for Irish populations.

Materials and Methods: We adopted and modified a bait deployment strategy developed by researchers in the UK. Bespoke baits were presented at setts targeted for control over a six-day period prior to trapping. Six baits were presented at sett entrances on each day using the following protocol:

Day 1 – naked baits (biomarker 1)
 Day 2 – naked baits (biomarker 1)
 Day 3 – packaged baits (biomarker 1)
 Day 4 – packaged baits (biomarker 1)
 Day 5 – packaged baits (biomarker 2)
 Day 6 – packaged baits (biomarker 2)

By changing the biomarker in baits deployed later in the trial we simulated a “live” vaccine bait deployment on days 5 and 6.

Results: The results section cannot be completed yet, since we are still collecting data. Our baits will be deployed through the winter. Once we have collated the results, I anticipate the section to be formatted in a similar manner to the outline below.

We presented bait at ## setts across Ireland between ## 2015 and ## 2016. ## % of trapped badgers had biomarker 1 present in blood serum (X1 out of Y1 animals). ## % of trapped badgers had biomarker 2 present in blood serum (X2 out of Y2 animals).

Comparative levels of the two biomarkers indicated that ## % of trapped badgers ate pre-baits prior to our simulated “live” vaccine bait deployment.

Conclusions: This section cannot be properly formatted as we do not have any results yet.

We aim to answer these questions:

Q. How many baits per day are best for Irish setts?
 A. Are 6 baits per sett per day enough?

Q. How many days of pre-baiting are needed prior to live vaccine deployment?
 A. How many of the badgers were found to have biomarker 2 in their blood serum?

Comments: While it is not possible to provide results at this point, we are confident that we will have all the data collected and analysed in time for the conference.

TU2-018-007

Bovine tuberculosis in cattle and red deer in Southern Bavaria, Germany – can network analysis explain the routes of transmission?Julia Boenchenndorf ^{1,*} Helmut Hartmann ² Johannes Bracher ³ Hartmut Lentz ⁴ Gabriela Knubben-Schweizer ¹ Carola Sauter-Louis ⁴

¹Clinic for Ruminants, Ludwig-Maximilians-University Munich, Oberschleissheim, ²Bavarian Ministry for Food, Agriculture and Forestry, ³Faculty of Statistics, Ludwig-Maximilians-University, Munich, ⁴Institute for Epidemiology, Friedrich-Loeffler-Institut, Greifswald - Insel Riems, Germany

Objectives: From 2000 onwards, increasing numbers of bovine tuberculosis outbreaks were reported in Southern Bavaria, Germany. The disease was observed in cattle and wild-living red deer with results of DNA fingerprinting indicating a transmission both within and across host species. The objective of our study was to describe the spread and transmission of the disease amongst cattle using network analysis and overlaying the geographical information of cattle grazing areas with locations of TB-positive hunted deer. Additionally we wanted to gain further knowledge on the epidemiological relevance of alpine pastures in the current outbreak.

Materials and Methods: Data on TBcases in cattle and movement data of cattle originating from holdings localized in the Bavarian districts bordering the Alps were obtained from the national database for cattle and swine (HITDatenbank) and covered the study period from 2010 to 2014. Data on bTBcases in red deer were collected within the framework of the European study EMIDAERANet and of the regional follow-up study, the Bavarian TBMonitoring in red deer. Two networks were visualized: An egocentric contact network consisting of the contacts of TBpositive cattle and a trade network representing cattle movements between holdings that had been visited by positive cattle. Regression analysis was used to identify risk factors for cattle holdings.

Results: The contacts and movements of bTBpositive cattle could account for a noticeable amount of positive bTB results in cattle holdings, but not for all. Therefore, factors additional to the contacts and movements of cattle tested positive for bTB must have contributed to the spread of bTB in the alpine region of Bavaria. The calculated centrality measures reflecting the exposition (indegree, eigenvector centrality) and the potential of holdings to spread infection (outdegree, betweenness centrality) both seemed to correlate with the infection status of cattle holdings. These correlations could be used to identify cattle holdings potentially at risk of infection in riskbased surveillance or during future outbreaks. Alpine pastures visited by bTB-positive cattle and *M. caprae*-cases in red deer overlapped to a large extent in the region "Allgäu" suggesting inter-species transmission in this area. All applied methods identified alpine pastures to be crucial for the spread of bTB in the alpine Bavarian districts.

Conclusions: The combination of spatial description, network and regression analyses could provide valuable insights into the epidemiology of bovine tuberculosis in the alpine region of Bavaria and indicated the importance of summer pastures for disease spread.

UH1-011-001

Use of infrared thermography to diagnose mastitis in pre-partum dairy heifers

Patricia Simoes ^{1,*}, Timothy Geraghty ², Lorenzo Viora ¹, Dominic McCafferty ³, Ruth Zadoks ³

¹Scottish Centre for Production Animal Health and Food Safety, School of Veterinary Medicine, College of Medical Veterinary and Life Sciences, University of Glasgow, Bearsden Road, Glasgow G61 1QH, ²SAC Consulting Veterinary Services, SRUC Aberdeen Campus, Craibstone Estate, Aberdeen AB21 9YA, ³Institute of Biodiversity, Animal Health & Comparative Medicine, University of Glasgow, Glasgow G61 1QH, United Kingdom

Objectives: Heifer intramammary infection (IMI) in early lactation impacts negatively on milk production and longevity in the herd, and is associated with a higher risk of subclinical and clinical mastitis. The origin of heifer IMI remains uncertain, in part due to the challenge of establishing when infection occurs, making the targeting of preventative methods difficult. Generally, it requires use of invasive techniques to collect mammary secretion pre-partum, which can themselves increase the risk of infection. Therefore, the aim of this study is to evaluate the usefulness of thermography as an early detection system for abnormal udder health.

Materials and Methods: The study was conducted on one commercial dairy farm of 700 lactating animals. One hundred twenty Holstein-Friesian heifers in the last trimester of pregnancy were enrolled in this field study. All heifers were submitted twice to infrared thermography (IRT); the first and second sets of thermograms were taken approximately two months and two weeks prior to the estimated calving date, respectively. A FLIR E300 infrared camera (FLIR Systems Inc., Wilsonville, USA) was used for all the IRT measurements. Each set of thermograms included two projections of the udder, one caudocranial and one ventrodorsal, from a distance of 0.70m. Ambient temperature, shed humidity and rectal temperature were measured and recorded. IRT images were analysed using ThermoCAM Research 2.10 Pro (FLIR Systems, Danderyd, Sweden). Different analysis tools (polygons, lines and spot meters) were applied to obtain a set of descriptive parameters, including 'min', 'max', 'max-min' and average. At calving, individual quarter samples were collected aseptically for milk culture using standard aerobic bacteriology and for measurement of somatic cell count (SCC) by means of fossomatic. In addition, clinical mastitis data and DHI-measurements of SCC over the first 100 days of lactation were recorded. Statistical analysis has been performed using SPSS version 17.0 (SPSS Inc., Chicago, USA).

Results: The synchronization of IRT image collection with farm routines allowed an easy, fast and non-stressful procedure. From the initial one hundred and twenty heifers, six were lost to follow up (two before 50DIM, four were sold before 100DIM). A Pearson product-moment correlation coefficient was computed to assess the relationship between the 'max' temperature of back quarters areas in caudocranial and ventrodorsal projections. Overall, there was a strong positive correlation between both projections at first IRT (left $r=0.70$, $P<0.0001$; right $r=0.63$, $P<0.0001$) and second IRT (left $r=0.62$, $P<0.0001$; right $r=0.54$, $P<0.0001$). At calving 37% ($n=161$) of the 440 quarters were culture-negative with geometric mean SCC of 188,000 cells/ml, 33% ($n=147$) presented <10 colonies with geometric mean SCC of 187,000 cells/ml, 25% ($n=109$) presented IMI (≥ 10 colonies) and geometric mean SCC of 421,000 cells/ml; and 5% were contaminated ($n=23$; ≥ 3 different morphotypes). SCC was higher for quarters with IMI than for culture-negative quarters or those with <10 colonies (Students' t -test; $P<0.001$ and $P<0.01$, respectively). Negative correlation was found between 'max' temperature at first IRT and SCC of IMI quarters ($r=-0.74$, $P<0.0001$).

Conclusions: Preliminary results of the study indicate that a ventrodorsal projection of the udder can be used to obtain a representative IRT image of the quarters, which may be useful in the most common handling facilities available in heifer rearing units, cattle race or crush. Thermography 2 months pre-partum may give earlier indications of IMI than SCC at first milking. Further analysis of IRT descriptive parameters, SCC and microbiology data will provide additional information on the capacity of IRT to detect naturally occurring mastitis under field conditions.

UH1-011-002

Milk microbiome assessed through 16S rRNA sequencing during antimicrobial treatment of mastitis - A Randomized Clinical Trial

Erika Ganda ^{1,*}, Rafael Bisinotto ¹, Dean Decter ¹, Kristina Kronauer ¹, Svetlana Lima ¹, Rodrigo Bicalho ¹

¹Population Medicine and Diagnostic Sciences, Cornell University, Ithaca, United States

Objectives: Specific aims were: 1) evaluate the effect of antibiotics on cure of culture negative and Gram-negative bacteria associated clinical mastitis; 2) use next generation sequencing to assess the microbiome of milk samples from mastitic quarters and compare it to the microbiome of ipsilateral healthy quarter of cows diagnosed with mild or moderate mastitis caused by either a Gram-negative pathogen or with no bacterial growth on conventional aerobic culture; and 3) evaluate the over-time effect of prolonged antibiotic therapy on microbial profiles of mastitic milk.

Materials and Methods: Cows diagnosed with clinical mastitis with a Gram-negative pathogen or no visible growth on on-farm culture ($n=103$) were randomly allocated into Treatment group, which received 5 intramammary infusions of ceftiofur hydrochloride at 24-h intervals on the affected quarter, or Control. Serial samples were collected before intramammary infusion of antibiotics on days 1, 2, 3, 4, 5, 8, 10 and 14 after enrollment from the affected quarter and an ipsilateral quarter for microbiome analysis. The V4 hypervariable region of the bacterial 16S rRNA gene was amplified from genomic DNA by PCR and sequenced using the Illumina MiSeq platform (Illumina, Inc., San Diego, CA, USA). Sequences were processed via the MiSeq Reporter version 2.5 and QIIME version 1.7.0-dev, for classification of reads, quality filtering, and calculation of number of OTUs, Chao1, and Shannon diversity indexes.

Microbiome changes occurring over time and in response to intramammary antibiotic therapy were analyzed at the phylum and family levels using JMP Pro 11. The mean relative abundance in healthy quarters was used as reference for calculation of fold-changes. Comparison of the microbiome was performed using response screening analysis to assess the effect of clinical mastitis on the relative abundance of bacterial families. P-values were adjusted for false discovery rate.

The GLIMMIX procedure of SAS was used to assess the effects of clinical mastitis and intramammary treatment in OTU numbers, Shannon, and Chao1 indexes.

Results: The relative abundance of bacteria from the phylum Proteobacteria was greater ($P < 0.01$) in the milk from mastitic quarters infected by *E. coli* and *Pseudomonas* sp. compared with that of healthy quarters, driven mostly by greater abundances of Enterobacteriaceae ($P < 0.001$) and Pseudomonadaceae ($P = 0.03$). The average abundance of Firmicutes, Actinobacteria, Bacteroidetes, Tenericutes, Chlorobi, and the combination of remaining phyla was greater ($P < 0.05$) in healthy compared with mastitic quarters.

As opposed to cases of clinical mastitis associated with specific pathogens, major shifts in bacterial populations were not observed in the milk of mastitic quarters classified as negative culture by standard laboratory methods.

Intramammary treatment with ceftiofur hydrochloride did not improve clinical and bacteriological cures of mastitis compared with untreated controls. In cows diagnosed with *E. coli* associated mastitis, the mean relative abundance of Enterobacteriaceae decreased from study day 1 to 14 (62.6 vs. 9.7%) and no differences in the rate of change of this bacterial group were observed between groups that received intramammary treatment with ceftiofur hydrochloride or control. Overrepresentation of individual families and defined time-related changes in milk microbiome were not observed in cows affected by clinical mastitis associated with culture negative. Moreover, intramammary treatment with ceftiofur hydrochloride did not result in major shifts on milk microbiome from mastitic quarters in the culture negative group.

Conclusions: Next generation sequencing revealed significant differences in the metagenome of healthy and mastitic quarters from cows diagnosed with Gram-negative pathogens. However, the bacterial profile of healthy and mastitic quarters from cows diagnosed with no bacterial growth under aerobic conditions did not significantly differ.

There were no significant differences in clinical cure or relative abundance of the most abundant bacterial family from mastitic samples between treatment and control groups in any of the bacterial groups evaluated.

UH1-011-003

The effect of sampling techniques on microbial species in quarter milk samples

Mari Friman ^{1,*}, Heidi Hiitö ¹, Mari Niemi ¹, Satu Pyörälä ¹, Heli Simojoki ¹

¹Faculty of Veterinary Medicine, University of Helsinki, Mäntsälä, Finland

Objectives: Milk samples give important knowledge on the aetiological agent causing mastitis. Bacteriological results of the milk samples are affected by many factors like sampling technique or the amount of bacteria in the milk.

The purpose of this study was to determine the effect of two different milk sampling techniques on bacteriological results from a PCR mastitis assay. Two different milk sampling techniques were evaluated: conventional manual aseptic sampling by milking (group A) and experimental sampling technique via the teat canal using a sterile cannula (group B).

Materials and Methods: The study was carried out on 44 commercial dairy farms during routine calls of the Production animal hospital of the University of Helsinki, Finland, from March 2011 to April 2013. A cow was included in the study if the Californian mastitis test (CMT) score in the milk of the affected quarter was ≥ 3 on a scale from 1 to 5. A case with clinical signs of mastitis in the milk of the quarter was recorded as clinical mastitis (CM) and a case with no clinical signs but an increased CMT score (≥ 3) as subclinical mastitis (SCM). A total of 88 cows were sampled and the total number of sampled quarters was 150.

The milk sampling technique was as follows: The teat was cleaned by removing visible dirt. Some squirts of milk were discarded and then milk was tested with CMT. Teat was disinfected with cotton wool moistened with 70% alcohol three times. Conventional samples (sample A) were first drawn to a 10-ml plastic milk tube (Linkoputki Plastone without preservatives, Mekalasi, Finland). Teat end was then disinfected again

and a sterile disposable teat cannula (Teat cannula, Vetcare, Finland) was pushed through the teat canal and sample B was taken to a 10-ml plastic milk tube. Somatic cell count (SCC) was measured with an electronic cell-counter DCC (DeLaval International AB, Sweden) in the laboratory (Production animal hospital) within six hours. Bacteriological examination of the samples was carried out with a Real-Time PCR assay (PathoProof™ Mastitis Complete-16 Kit, Thermo Fisher Scientific Ltd, Finland). The statistical analysis (chi, kappa) was done with Stata IC.

Results: In total, 100 SCM samples (SCC in average 1 249 000 cell/ml) and 50 CM samples (SCC in average 2 327 000 cell/ml) were included. SCC result was missing from 22 samples. Samples of group A comprised more microbial species than samples of group B ($p=0.00$). Samples of group A comprised 18% less samples with one species only than those in group B. More samples with 3 and ≥ 4 species detected were found in group A than in group B (samples with 3 species: 19 in A vs 6 in B; samples with ≥ 4 species: 14 in A vs 4 in B).

The microbial findings were different according to the sampling technique. The occurrence of many microbial species was lower in the milk samples taken with the cannula technique (group B). Coagulase-negative staphylococci (CNS) was a very common finding in both groups, and was detected more often in group A samples (83 samples) than in B samples (68 samples) (a decrease of 18%). As many as 35 A samples were positive for yeasts but only 15 B samples (a decrease of 57%). *Streptococcus dysgalactiae* was detected in 23 A samples and in 11 B samples (a decrease of 52%) and *Trueperella pyogenes/Peptoniphilus indolicus* was detected in 17 A samples and 6 B samples (a decrease of 65 %). The sampling technique did not affect the prevalence of *C. bovis*; 26 samples positive in group A and 23 samples positive in group B, kappa value (k)=0.63 indicating a substantial agreement between techniques. Kappa values of yeast ($k=0.14$) and *Trueperella pyogenes/Peptoniphilus indolicus* ($k=0.31$) indicated that cannula technique decreases the occurrence of those microbes in the samples.

Conclusions: Our results show that conventional milk sampling technique is more prone to contamination than the experimental cannula technique. More multi-species samples were found with the conventional technique. The cannula technique particularly reduced the occurrence of yeasts and *Trueperella pyogenes/Peptoniphilus indolicus*. Cannula technique improved the quality of quarter milk samples, but is not feasible as a routine method. Our results emphasize the importance of a careful aseptic technique in the conventional milk sampling, which is still the method of choice in daily work.

UH1-011-004

The interest of dairy farmers in mastitis diagnostics

Karien Griffioen ¹, Geralda E. Hop ², Manon M. Holstege ², Annet G. Velthuis ^{2,*}, Theo J. Lam ^{1,2} and the Dutch Mastitis Diagnostics Consortium

¹Faculty of Veterinary Medicine, Farm Animal Health, Utrecht University, Utrecht, ²GD Animal Health, Deventer, Netherlands

Objectives: The aim of the study was to determine the use of bacteriological diagnostics for clinical mastitis (CM), subclinical mastitis (SCM), and dry cow treatment (DCT) by Dutch dairy farmers. Additionally their interest in diagnostic tests and the characteristics they consider important were determined.

Materials and Methods: A telephone interview was conducted among 195 randomly selected Dutch dairy farmers, with a herd size of >20 adult

cows. For the telephone interview, a structured questionnaire was used, based on previously held face-to-face interviews with 20 non-randomly selected Dutch dairy farmers. The questionnaire consisted of a general part regarding background information of the farmer, udder health consultancy services on the farm and udder health characteristics. The specific part of the questionnaire discussed the farmers' current diagnostic and treatment approach, their interest in mastitis diagnostics, and the desired test characteristics of mastitis diagnostics for CM, SCM and DCT. The answers were registered in a database and were analysed using descriptive statistics and univariable and multivariable models.

Results: A treatment decision for CM was mainly based on clinical signs. For SCM and DCT the most used criterion was somatic cell count. Bacteriological culture (BC) is used by 34% of the farmers for CM cases, and 2% used the results for treatment decisions. If an on-farm test that would reveal the preferred treatment for CM within 12 hours would be available, 71% of the farmers indicated they would use it. For SCM and DCT, 55% and 34% respectively, indicated they were willing to use such an on-farm test, where 22% and 7% respectively, indicated to use BC currently.

Farmers were most often interested in 'the preferred treatment' as test outcome for CM (58% of the farmers) and DCT (15% of the farmers). For SCM the test outcome of interest was the causative bacterium (38% of the farmers). Farmers already using BC were 13.1 times (95% CI = 3.1-55.6) more likely to express their interest in the preferred treatment as test outcome for CM than farmers who do not use BC. Fourteen percent of the farmers were not interested at all in mastitis diagnostics for CM, increasing up to 28% and 55% for SCM and DCT, respectively.

Reliability was indicated most often as an important test characteristic for CM, SCM and DCT. Time-to-result (TtR) was for CM the second most important whereas for SCM and DCT, TtR was the least important. The median of the farmers indicated the preferred TtR as <8 hours for CM and 22-24 hours for SCM and DCT. Furthermore, a price of €10,- to €15,-, a hands-on-time of 7.5-10 minutes and <7% false outcomes were indicated as acceptable for CM, SCM and DCT.

Conclusions: Dutch dairy farmers are interested in mastitis diagnostics, specifically for CM. The use of mastitis diagnostics will likely increase when a reliable on-farm test that reveals the preferred treatment and with a suitable TtR is available.

UH2-012-001

A cost-effectiveness analysis of on-farm culture for the treatment of clinical mastitis in dairy cows

Peter Down ^{1,*}, James E. Breen ^{1,2}, Andrew J. Bradley ^{1,2}, Martin J. Green ¹

¹School of Veterinary Medicine and Science, University of Nottingham, Loughborough, ²Quality Milk Management Services Ltd, Wells, United Kingdom

Objectives: The use of on-farm culture (OFC) as a means of selectively treating cases of clinical mastitis in dairy cows has been reported recently (Lago et al., 2011) and is increasingly being advocated as a rational approach to reducing the use of antimicrobial drugs on dairy farms. The purpose of this research was to use probabilistic sensitivity analysis to investigate the cost-effectiveness of OFC. A particular aim was to identify scenarios when OFC was likely to be cost-effective and, therefore, the types of herds for which an OFC approach could reasonably be recommended.

Materials and Methods: The model used was an adaptation of a previously published cost-effectiveness model (Down et al., 2013), with the addition of OFC-specific parameters based on previous research (Lago et al., 2011). A stochastic Monte Carlo model was implemented to repeatedly simulate the cost of a case of clinical mastitis that could be treated according to two different methods; i) a standard approach (3 tubes of intramammary antibiotic), ii) an OFC programme as described by Lago et al., (2011). Model parameters were based on values taken from the current literature where possible and 5000 model iterations after convergence were used.

Spearman rank correlation coefficients were used to evaluate the relationships between model parameters and net cost effectiveness of the different treatment approaches. Further scenario analyses were performed to identify key parameters that determined the probability that OFC was more cost-effective than the standard approach.

Results: The Spearman rank correlation coefficients revealed that the proportion of culture-negative cases and the difference in bacteriological cure rates had the largest impact on the probability that the OFC approach was more cost-effective than the standard approach. The magnitude of these values suggested that OFC may not be cost effective in a considerable number of dairy herds. Other model parameters that were correlated with the difference in cost-effectiveness were the milk withdrawal period, the cost of drugs, the time taken to treat the cow (and culture) and the rate of transmission from an infected cow to an uninfected herdmate.

The scenario analysis indicated that the OFC approach was most likely to be cost-effective when the proportion of culture-negative cases was at least 53% and when the bacteriological cure rate was not more than 5% poorer in the OFC group compared to the standard treatment group. It was also evident that if the bacteriological cure rate was approximately 11% worse in the OFC group than in the standard treatment group, then the proportion of culture-negative cases would need to be at least 79% to make OFC cost-effective.

Conclusions: The results of this study indicate that the proportion of culture -ve cases and the bacteriological cure rate have the greatest impact on the probability that an OFC approach would be more cost-effective than a standard approach. The OFC approach would be most suitable for herds in which Gram -ve pathogens are responsible for most clinical mastitis and where the treatment of cows according to the results of an OFC approach results in minimal reductions in the bacteriological cure rates. Results suggest caution should be exercised in using OFC without a transparent message that the method will probably not be cost-effective for many herds.

Discriminating *Staphylococcus aureus* isolates from other common mastitis pathogens in dairy cows with scent dogs

Carola Fischer-Tenhagen ^{1,*}, Viviane Theby ¹, Volker Krömker ², Wolfgang Heuwieser ¹

¹Clinic of animal reproduction, FU Berlin, Berlin, ²Institut of Microbiology, Hanover University of Applied Science and Arts, Hannover, Germany

Objectives: The objective of this study was to proof that bacteria causing mastitis in dairy cows can be identified by their specific odor. Specifically we set out to train dogs to discriminate the odor of *Staphylococcus aureus* against five other common mastitis causing agents. The study included two experiments. First we tested if dogs can discriminate *Staph. aureus* in the headspace of blood agar plates growing *Staph. aureus* colonies. In the second experiment the dogs had to identify the odor of *Staph. aureus* in milk samples spiked with *Staph. aureus* or the other infectious agents, respectively.

Materials and Methods: 10 privately owned dogs of various breeds and both sexes were trained in this study. For the first experiment bacteria were isolated from milk samples from cows with clinical mastitis and cultured on Columbia Agar with 5% sheep-blood for 48 h. Identification of infectious agents was by their morphology and was confirmed by MALDI-ToF. Until use, strains were stored at -20°C in cryotubes. Before dog training or testing the infectious agents were again cultured on Columbia Agar with 5% sheep-blood. A cotton swab was placed in the lit of the plate to absorb the specific odors. For the second experiment only *Staph. aureus*, *Strep. uberis* and *Enterococcus* spp. were used. Bacteria were concentrated (10^{12} CFU/g) and frozen at -20°C in cryotubes. For dog training and testing the bacterial concentrate was solved in 2 ml fresh bulk tank milk with SCC 120 000/ml. The cotton swabs or milk sample were placed into a 1 liter sterile plastic buckets with perforated lits. The tests for each experiment included 10 test trials. For one trial a dog had to discriminate one sample containing *Staph. aureus* against nine samples containing other infectious agents. Every dog tested 100 samples.

Results: Eight dogs completed the training and took part in the test of the first experiment. The training duration in minutes varied from 111 – 290 min (163.4 ± 70.2 min). Overall sensitivity for identifying *Staph. aureus* in the head space of agar plates against five other common mastitis causing agents (i.e., *Escherichia coli*, *Streptococcus uberis*, *Streptococcus dysgalactiae*, *Pseudomonas aeruginosa* and *Candida albicans*) was 91.3% and specificity was 97.9 %. Four dogs did not make any mistakes. Breed or sex of the dog had no influence on the performance. Six dogs were included in the second experiment. In bulk tank milk the dogs could identify the samples with *Staph. aureus* against *Strep. uberis* and *Enterococcus* spp. with a specificity and sensitivity of 82% and 87%, respectively.

Conclusions: In this study we demonstrated that *Staph. aureus* can be identified by means of a specific odor in two substrates. Further research is warranted to proof that odor diagnostic either with technical methods such as gas chromatography or electronic noses devices or biosensors such as trained animals (e.g., rats, bees or dogs) could be a valid and practical diagnostic tool to identify mastitis pathogens.

UH2-012-003

Potentials and challenges for diagnosis of contagious udder pathogens with realtime PCR tests from samples at milk recording

Ilka Christine Klaas ¹, Yasser Mahmmod ², Jørgen Katholm ³, Søren S. Nielsen ¹, Carsten Enevoldsen ¹

¹Department of Large Animal Sciences, University of Copenhagen, Frederiksberg, Denmark, ²Department of Veterinary Population

Medicine, University of Minnesota Twin Cities, Minneapolis, United States, ³DNA Diagnostic A/S, Risskov, Denmark

Objectives: Accurate diagnosis is necessary to control contagious udder pathogens in dairy herds. Since 2009 Danish farmers can order PCR analysis of routinely taken milk recording samples. The PCR test has higher sensitivity for detection of *Staphylococcus* (S.) *aureus* and *Streptococcus* (S.) *agalactiae* than bacteriologic culturing, but is carried out on non-aseptically taken samples. Thus, carry-over between cows and false positive results due to contamination may occur. Our objectives were to investigate carry-over effects between consecutively milked cows and the effect of teat preparation on PCR test results for S. *agalactiae* and S. *aureus*.

Materials and Methods: A total of 1,199 dairy cows from six herds infected with S. *agalactiae* and S. *aureus* were included in the study. Bronopol preserved composite milk samples were taken at the routine milk recording between March and May 2011 after the farm personnel had carried out their routine pre-milking practices. All samples were tested using the PathoProof Mastitis PCR assay and results recorded as cycle threshold (Ct)-values. Aseptically sampled quarter foremilk were subjected to bacteriological culturing for S. *aureus* and for S. *agalactiae* in 50% randomly selected cows, i.e. all cows milked at every second milking unit. Data on parity, somatic cell counts, days in milk, and kg energy corrected milk were obtained from the Danish Dairy Cattle Database.

Logistic regression including herd as random effect was used to investigate the effect of teat disinfection on S. *aureus* PCR positivity. Milking order was available from four herds. The effect of milking order on S. *agalactiae* PCR positivity was investigated applying logistic regression with generalized estimating equations. The effect of the Ct-value for S. *aureus* of the previously milked cow on the Ct-value of the subsequent cow was investigated with a multinomial logistic regression model. Five cut-off categories for PCR Ct-values were chosen: 0-31.3; 31.4-33.9; 34.0-37; 37.1-39.9; and 40.

Results: Teat preparation including teat disinfection reduced the odds of being PCR positive for S. *aureus* (OR 0.75, Mahmmod et al. 2013), but not for S. *agalactiae*. Carry-over in terms of correlated PCR results (Ct-values) of cows milked consecutively occurred (Mahmmod et al. 2014). The correlation was 13%, 11%, 9% at S. *agalactiae* Ct-value cut-offs 39, 37, and 34, respectively.

The multinomial logistic regression model showed that the Ct-value category for S. *aureus* of the preceding cow had a large impact on the Ct-value category of the subsequently milked cow. If the previously milked cow was classified as PCR negative (Ct-value 40), the subsequently milked cow at the same milking unit was approximately three times more likely to be PCR negative (prevalence 60%) in comparison to cows that were milked after a cow in the PCR category 0-31.3 (prevalence 20%).

Conclusions: Milk samples for PCR diagnostics should preferably be taken aseptically, especially if information on milking order and infection status of the previously milked cow is unavailable. Composite milk samples from milk recording can be used for PCR diagnostics of S. *agalactiae* and S. *aureus* if teats are disinfected and the milking order is known. Teat disinfection will reduce false positive results for S. *aureus*. Carry-over effects for S. *agalactiae* and S. *aureus* occur and have to be addressed by accounting for milking order, repeated testing of positive cows milked subsequent to a positive cow and by considering other inflammation markers.

UH2-012-004

Efficacy of Topical Treatment of Udder Cleft DermatitisTine van Werven^{1,2,*}, Jacintha Wilmlink³, Steven Sietsma², Mirjam Nielen¹¹Department of Farm Animal Health, Faculty of Veterinary Medicine, Utrecht University, Utrecht, ²University Farm Animal Practice, Harmelen, ³Woumarec, Wageningen, Netherlands

Objectives: Udder Cleft Dermatitis (UCD) is characterized by lesions of the skin between the front quarters or between the front quarters and the abdominal wall. UCD can be categorized into two groups, depending on the integrity of the skin. Mild cases are characterized by crusts, sebum, erythema or transudate, but with an intact skin, whereas severe cases are characterized by open wounds combined with pus and necrosis. To date no effective treatment has been proven which reduces the duration of UCD. The objective of this study was to investigate the efficacy of two different topical treatments for mild and severe cases of UCD.

Materials and Methods: A randomized clinical trial was performed on 8 Dutch dairy herds with a high prevalence of UCD. At T0 all cows present were inspected for signs of UCD and photos were taken from the affected animals. The lesions were photographed together with a ruler, so the length of the lesion could be measured. The photos were judged by an external wound expert who classified the affected animals in three different groups: mild lesions, severe lesions < 5 cm or severe lesions ≥ 5 cm.

Within each herd mild cases were randomized into a treatment group or control group, whilst severe cases were stratified into < 5 cm and ≥ 5 cm before they were randomized into treatment or control.

Cows that were included in the study were identified using different colored leg bands corresponding to treatment groups (mild or severe). Cows in the control groups were not identified, because they were not treated by the farmer. All farmers were supplied with treatment protocols and trained in how to treat the affected animals after milking. Treatment of the mild cases consisted of rubbing the affected area every other day with Cavulon®, a small foam wipe that should prevent skin breakdown. Severe cases were treated every day with 10 gram Botop®, an enzyme alginate. Cows were checked and photographed once a week and photos were sent to the wound expert who was blinded to the treatment and control groups. At the end of the 12 week study period cows could be cured, improved, unchanged, or deteriorated.

Results: Within-herd prevalence at T0 varied between 10% and 46%. Five out of eight herds had more mild than severe cases. A total of 206 animals were included in the study and were followed for a period of 12 weeks. From all affected animals 113 cases were mild (57 treated, 56 controls), 47 cases were severe < 5 cm (25 treated, 22 controls) and 46 cases were severe ≥ 5 cm (25 treated, 21 controls).

In the group of the mild cases no significant difference was observed between the treated and the control animals. After 12 weeks 36.8% of the treated and 37.5% of the control animals were cured. Animals with severe lesions < 5 cm showed significant differences. In the treated group 28% of the cases were cured and 32% of the cases changed from severe to mild (improved), compared to 13.6% and 4.5% respectively in the control group (P < 0.01). In the treated severe cases ≥ 5 cm group 36% of the cases were improved compared to only 4.7% of cases improving in the severe control group (P < 0.05). Only a 2% cure was observed after 12 weeks in both the treated and control group. Overall results of the severe cases (<5 cm and ≥5 cm) showed 18% cure and 34% improvement in the severe treated group compared to 12% cure and 5% improvement in the severe control group.

Conclusions: No significant differences were seen in animals with mild lesions that were treated with Cavulon® compared to the control group. This might be due to the small format of the wipe which made it difficult

to treat the affected area. Treatment of the severe cases with Botop® however proved to be a successful therapy. Treated severe cases < 5 cm had a significantly higher cure rate than the controls, whereas the treated severe cases ≥ 5 cm showed significant improvement during the study period of 12 weeks, since 12 weeks was too short for total recovery. To our opinion this is the first study showing an effective treatment for severe cases of UCD.

UH2-012-005

The Efficacy Of A Novel Combination Intramammary Treatment For Mastitis In Dairy Cows In New ZealandMark Bryan^{1,*}, Shen-Yan Hea², Sally Mannering³, Richard Booker⁴, Matt Wells⁵¹Head of R&D, ²Epidemiologist, VetSouth Ltd, Southland, ³Estendart Ltd, Palmerston North, ⁴Stockguard Laboratories, ⁵Technical Services Manager, Virbac, Hamilton, New Zealand

Objectives: The two most common udder pathogens found in clinical mastitis in New Zealand dairy cows are *Staphylococcus aureus* and *Streptococcus uberis*. Traditionally, cloxacillin is recognized as the choice of treatment for the former and penicillin for the latter, which leads to some challenging therapeutic decisions, further complicated by the presence of resistance in the former pathogen. This large scale field study was designed to test the non-inferiority of a novel combination intramammary product containing penicillin and cloxacillin under field conditions in New Zealand, with regards to bacteriological cure and clinical cure proportions.

Materials and Methods: Clinical cases of mastitis were sourced from 30 spring-calving dairy farms in the Southland region of New Zealand. Affected quarters were infused three times at 24 hourly intervals with either the novel combination product containing 1g penicillin and 200mg cloxacillin, or a reference product containing 200mg oxytetracycline, 100mg oleandomycin, 100mg neomycin and 5mg prednisolone. Cows were enrolled when a farmer detected a case of clinical mastitis. Milk samples were collected for microbiological culture immediately before treatment (day 0) and on days 9, 16 and 23 after enrolment. A total of 235 quarters treated with reference product and 223 quarters treated with the novel combination product were eligible for per protocol analysis. Non-inferiority was assessed by calculating the difference in cure rates between the two products and constructing a 95% confidence interval around the difference. The confidence interval around the difference was inflated by the square root of the variance inflation factor (VIF) to account for herd level clustering. The non-inferiority margin (δ) was 20% for both bacteriological cure and clinical cure. The effect of covariates on bacteriological cure and clinical cure rates were assessed using Generalizing Estimating Equations (GEE) to account for herd level clustering.

Results: A total of 93 cases (20.3% of all cases) were recorded as having no clinical cure during the follow up period. Clinical cure occurred in 79.6% of cases treated with the reference product, and 79.8% of cases treated by the novel combination product. The clinical cure proportion was 0.3% (-11.2%, -12%) higher for clinical quarters treated with the novel combination product, which was demonstrated to be non-inferior to the reference product with regards to clinical cure rates, as the lower confidence interval of the difference between treatments did not extend beyond the lower limit δ of -0.20.

Bacteriological cure occurred in 57.2% of cases treated with reference treatment and 65.7% of cases treated by the novel combination treatment. The bacteriological cure proportion was 8.51% (95%CI:

-1.7%, -21.8%) higher for clinical quarters treated with the novel combination product. The novel combination product was demonstrated to be non-inferior to the reference product with regards to bacteriological cure rates as the lower confidence interval of the difference between the treatments did not extend beyond the lower limit δ of -0.20. The adjusted cure rate for *S. aureus* was 17.6% higher for quarters treated with the novel combination product, however this difference was not significant ($P > 0.05$).

In addition, the novel combination product reduced somatic cell counts during the follow up period ($p = 0.053$). Pathogen type was a significant predictor on the bacteriological cure proportion, and quarter score at enrolment was a significant predictor on the clinical cure proportion.

Conclusions: The novel combination product was demonstrated to be non-inferior to the reference product with regards to both bacteriological cure proportion and clinical cure proportion. Under field conditions where Gram positive mastitis pathogens are predominant this combination of antimicrobials is an efficacious treatment.

Thus, this novel combination intramammary product provides appropriate and effective treatment for both *S. uberis* and *S. aureus* under New Zealand field conditions. Using a combination product where there is a risk of antimicrobial resistance also reduces the risk of developing resistance within a pathogen class.

Comments: This study was funded by Virbac (NZ) Ltd (formerly Stockguard Laboratories Ltd).

UH2-012-006

Evaluation of Intramammary Infusion of Lactic Acid Bacteria and Therapeutic Effects on Mastitis in Dairy Cows

Hajime Nagahata¹, *Moe Horiguchi¹, Satoshi Gondaira¹, Hidetoshi Higuchi¹

¹Rakuno Gakuen University School of Veterinary Medicine, Ebetsu, Hokkaido, Japan

Objectives: Development of alternative therapeutic approaches to antibiotics is of increasing concern for control of mastitis. The objective of the study was to characterize the cellular and immune responses of mammary gland by intramammary infusion of lactic acid bacteria (LAB) in dairy cows, and to evaluate the therapeutic effects of LAB to lactating cows with mastitis.

Materials and Methods: Twelve Holstein cows were used to analyze the cellular and immunological effects of mammary glands by infusion of *Bifidobacterium breve* (*B. breve*, heat-killed 3×10^9 cfu) was used. Thirty-eight cows with subclinical mastitis were used for evaluation of therapeutic effects of *B. breve*. Milk samples were collected from the quarters prior to infusion and 1, 5, 7, 14 and 21 days post infusion. Somatic cell counts (SCC), milk composition, N-acetyl-glucosaminidase (NAGase) activity and mastitis-causing pathogens, lactoferrin (Lf), immunoglobulins in quarter milk were determined. Chemiluminescence response in milk, cytokine mRNA (IL-1 β , TNF- α , IL-6, 8, NF- κ B) on milk leukocytes and their cytokines were determined.

Results: Significant increases in SCC, NAGase activity were found at 1-2 days post infusion and their values decreased after 3-5 days post infusion. Ten to 30 fold increases in numbers of SCC were found in milk from quarters at 1-2 days after infusion of LAB. Significantly increased concentrations of Lf, IgG and IgA, and increased mRNA

expression of cytokines IL-1 β , TNF- α , IL-6, 8 on milk leukocytes were found in cows at 1-3 days after intramammary infusion. The therapeutic trials of intramammary infusion of LAB were evaluated in dairy cows with subclinical mastitis: bacteriological cure rates (< 300 cfu/ml) were 64.7% (11/17) for environmental streptococci, 66.7% (8/12) for CNS, 0-20% (1/7) for *Staph. aureus* at 7-14 days post infusion. Mean SCCs in 14 quarter milk with no bacteria growth were significantly decreased at 14 days post infusion.

Conclusions: Intramammary LAB infusion promotes the clearance of the pathogens causing mastitis from quarters and alleviates the local infection in affected quarters from cows with subclinical mastitis. Intramammary infusion of LAB may be a possible approach for non-antibiotic treatment for mastitis.

UH2-012-007

Application of Multilocus Sequence Typing in *Streptococcus agalactiae* isolated from Bovine Mastitis in China

Shiyao Zhang¹, *Limei Zhang¹, Bo Han¹

¹College of Veterinary Medicine, China Agricultural University, Beijing, China

Objectives: To investigate the occurrence and distribution of *Streptococcus agalactiae* (*S. agalactiae*) from bovine clinical mastitis and subclinical mastitis in different regions of China and to assess the molecular epidemiology and population structure of the Chinese isolates.

Materials and Methods: Twenty-three isolates of *S. agalactiae* were recovered from the milk of cows with bovine Clinical and subclinical mastitis in four provinces (Beijing, Anhui, Hebei, Heilongjiang) of China between 2014 and 2015. The identification of *S. agalactiae* was done by Edward Medium (modified), biochemical method and Polymerase Chain Reaction (PCR) with 16S rRNA gene sequence. Application of multilocus sequence typing (MLST) was to establish the clonal groups. Fragments (459 to 519 bp) of seven housekeeping genes (*adhP*, *PheS*, *atr*, *glnA*, *sdhA*, *glcK*, *tkt*) were amplified by PCR for each strain and sequenced. The combination of alleles at the seven loci provided an allelic profile or sequence type (ST) for each strain. The entire *S. agalactiae* MLST database and eBURST program were used to analyze global clonal complex (GCC).

Results: Fifteen *S. agalactiae* isolates were recovered from the 121 cases of clinical mastitis and eight *S. agalactiae* isolates were recovered from the 87 cases of subclinical mastitis. Ten *S. agalactiae* isolates were recovered from Beijing, Six from Hebei, five from Heilongjiang and two from Anhui. All the twenty-three *S. agalactiae* isolates from bovine mastitis in China were identified by MLST to possess a similar allelic profile ST-103. The eBURST analysis of *S. agalactiae* MLST data showed that ST-103 was in GCC103, which remained as a distinct group.

Conclusions: *S. agalactiae* was the most common pathogen isolated from the bovine Streptococcal mastitis in China. ST-103 was emerged as a highly prevalent clone in bovine clinical and subclinical mastitis among different regions of China.

Comments: This study provided useful information for further studies on the genotyping and evolutionary research for *S. agalactiae* strains with global diversity. The assay will be useful for the development of vaccines against mastitis caused by *S. agalactiae*, as well as for the

treatment and control of bovine mastitis. This research was supported by No. 2012BAD12B03, No. 313054, No. 20120008110042 and No. 31572587.

YS1-048-001

Risk factors for calf mortality and poor growth of dairy heifer calves in GermanyAnnegret Tautenhahn ^{1,*}Kerstin-Elisabeth Müller ¹Roswitha Merle ²¹Clinic for ruminants, ²Institute for Veterinary Epidemiology and Biostatistics, Freie Universität Berlin, Berlin, Germany

Objectives: The objectives of this study were to investigate calf mortality rates, the average daily weight gain till weaning and factors associated with the risk of mortality and of poor growth in young dairy replacement heifers in Germany on a herd-level bases.

Materials and Methods: A case-control study was performed in 50 herds, which were selected based on acceptance to participate in the study and were located in northeast Germany. The experimental unit was the herd. Each herd was visited once between 2012 and 2014. A questionnaire on farm management practices, morbidity and calf mortality was completed by in-person interview. Furthermore colostral, blood und faecal samples were collected to check for colostral quality, failure of passive transfer (FPT), nutritional status and faecal pathogens causing neonatal calf diarrhea. Heart girth measurements were conducted around weaning (12th week) to assume average daily weight gain (ADG). Additionally a score concerning calf welfare was determined. The epidemiological associations between these factors with calf mortality and with poor growth were estimated by using two logistic regression models. In the first step all candidate variables were screened in univariable analysis and those associated with the outcome variable at $p \leq 0.20$ ($n=14/23$) qualified for multivariable analysis, but just 7 candidate variables each were selected. The initial multivariable models were reduced using a manual stepwise backward procedure, with $p < 0.1$ as criterion for retention. Variables excluded during the reduction were re-entered one by one after all remaining variables were significant ($p < 0.05$).

Results: The median calf mortality risk in calves 1–6 month of age was 5.0% (Range: 0.0–17.7%). The factors significantly associated with high calf mortality (>5.0%) were the application of Halofuginon ($p < 0.05$, OR: 6.7) and the access to hay in the first week of life compared to those offered no hay before weaning ($p < 0.05$, OR: 0.2). In the multivariable logistic regression model the factors application of Halofuginon ($p < 0.01$, OR: 10.0) and a high rate of calves with FPT ($p < 0.05$, OR: 8.1) explained 37.6% of the variation between herds with high and low calf mortality.

On herd-level the median ADG in calves 3 month of age was 675 grams per day (Range: 414–1027 g). The risk factors significantly associated with poor growth were offering hay before weaning ($p < 0.05$, -142 g), collecting first colostrum later than two hours after parturition ($p < 0.05$, -142 g), the amount of concentrates consumed at weaning ($p < 0.01$, +130 g per kg concentrates), changing the bedding in the calf pen at least once every two weeks ($p < 0.05$, -96 g), relocating calves more than twice from birth till weaning ($p < 0.01$, -93g), feeding less than 3.0 liters of first colostrum ($p < 0.05$, -88 g) and leaving the maternity pen more than two hours per day unattended ($p < 0.05$, -84 g). In the multivariable logistic regression model the factors amount of concentrates consumed at weaning ($p < 0.001$, +160 g per kg concentrates), relocating calves more than twice from birth till weaning ($p < 0.001$, -119g) and having an incidence of milk fever under 5% ($p < 0.01$, -115 g) explained 72.8% of the variation in growth of calves around weaning.

Conclusions: These results indicate that management practices in dairy farms rearing their own replacement heifers have an impact on calf mortality and on poor growth till weaning. They should be taken seriously concerning calf health and animal welfare.

YS1-048-002

Calving characteristics and physical examination parameters associated with abnormal underlying physiology in newborn beef calvesElizabeth R. Homerosky ^{1,*}Nigel A. Caulkett ²Edouard Timsit ¹Edmond A. Pajor ¹John P. Kastelic ¹M. Claire Windeyer ¹¹Department of Production Animal Health, ²Department of Veterinary Clinical and Diagnostic Sciences, University of Calgary Faculty of Veterinary Medicine, Calgary, Canada

Objectives: Abnormal physiology resulting from dystocia is associated with failed transfer of passive immunity, morbidity, and mortality in newborn calves. Modified Apgar scores developed to identify compromised calves are not widely used, apparently due to lack of practicality and inconsistent associations with underlying blood physiology. The objective was to evaluate associations of underlying blood physiology with physical examination parameters and calving characteristics to determine key parameters indicative of acidosis in newborn beef calves.

Materials and Methods: Data were collected from 77 dystocic and non-dystocic calves born on a large commercial cow-calf operation in Alberta, Canada (Spring of 2014). Blood parameters at 10 min and 24 h after birth were compared to calving characteristics and at-birth physical examination parameters. Parametric blood parameters were assessed using Student's t-test for dichotomous outcomes and ANOVA with Tukey-Kramer post hoc test for multiple comparisons. Wilcoxon test for dichotomous outcomes and Kruskal-Wallis with Dunn post hoc test for multiple comparisons were used for non-parametric variables. Repeated measures ANOVA was used to test main effects and interactions for all significant calving characteristics and at-birth physical examination parameters. Unconditional associations of blood parameters with continuous at-birth calving characteristics and physical examination variables, as well as lactate, were evaluated using Pearson correlation coefficients.

Results: Traditional Apgar score parameters, heart and respiratory rate, were not associated with pH or lactate ($r < 0.25$); however, lactate was strongly correlated with pH ($r = -0.86$). Mucous membrane colour (another traditional parameter) was not associated with pH ($P = 0.07$) but was associated with lactate ($P = 0.002$). Tests of muscle tonicity and reflexes, namely inability to completely withdraw the tongue when pinched and weak suckle reflex, were associated with both decreased pH and increased lactate ($P < 0.05$ for each). Calves born to primiparous dams or with increased calving difficulty also had decreased pH and increased lactate ($P < 0.05$ for each). Differences in pH between at-birth categories resolved for all parameters by 24 h after birth, except tongue withdrawal ($P = 0.04$).

Conclusions: Traditional Apgar parameters, heart and respiratory rate and potentially mucous membrane colour, may not consistently identify compromised calves with acidosis. Indicators of muscle tonicity and reflexes, such as degree of tongue withdrawal and strength of suckle reflex, as well as calving ease and parity, should be further examined. Additionally, hand-held meters to determine blood lactate concentration may be a useful on-farm tool for identification of acidotic calves.

YS1-048-003

The impact of colostrum on the microbiological health of the developing bovine intestinal tractBrian Aldridge ^{1,*}Elena Bichi ¹Jim Lowe ¹

¹Veterinary Clinical Medicine, University of Illinois, Urbana, United States

Objectives: Enteric disease is a major cause of morbidity and mortality in young calves. In recent years, studies have showed that beneficial commensal microbes contribute to intestinal health by supporting epithelial function, host metabolism and immune development. Microbial colonization begins with the acquisition of pioneer organisms from the dam. After this, composition of the microbiome varies but the most desirable trajectory is towards richness and diversity. In this study we studied the impact of colostrum on the bovine neonatal microbiome during the pre-weaning period.

Materials and Methods: A total of 12 healthy male Holstein calves were separated from the cow immediately following birth, and fed 4 liters of aseptically collected, high quality colostrum. All calves were housed, monitored, and fed separately for the remainder of the experiment. A group of 3 animals were euthanized for necropsy, and intestinal samples collected before colostrum administration (day 0) and progressively during the rest of the trial (days 3, 7 and 21). Intestinal mucosal and luminal samples were collected from the duodenum, jejunum, ileum and colon. The microbiome of these samples were analyzed using PCR with V3-V4 16S rRNA gene marker and the current generation MiSeq (Illumina) sequencing technology. Total microbial richness was assessed through rarefaction analyses and diversity was determined by Shannon's diversity indices, as well as the change in relative abundance of the important bacterial species.

Results: The intestinal samples were different from the stomach samples, especially comparing the digesta to scraping samples. The digesta samples had a large proportion of sequences unclassified at the family level, as well as rare families that had <1% abundance each. While Prevotellaceae was not in large abundance in the digesta samples, it was found in higher abundance in the proximal jejunum scrapings. Burkholderiaceae was found in some digesta from the jejunum and ileum and in large abundance in the duodenum, jejunum, and ileum scrapings. In the intestines and stomach, Enterobacteriaceae decreased over time, while Comamonadaceae increased over time.

Colostrum samples had a large proportion of sequences unclassified at the family level, and rare families that had <1% abundance each. Bacteroidaceae, Caulobacteraceae, Comamonadaceae, Flavobacteriaceae, Pseudomonadaceae, and Xanthomonadaceae all decreased over time, Lachnospiraceae maintained abundance, and Ruminococcaceae increased over time. The pharynx scrapings showed a decrease in Pasteurellaceae, Enterobacteriaceae, Clostridiaceae, and Streptococcaceae, with an increase in Comamonadaceae over time. Clostridiaceae was found in the pharynx at day 1 but no Clostridiaceae were found in colostrum at any sampling time. On day 7, a large proportion of Porphyomonadaceae, typically sugar fermenters, were found. Pasteurellaceae contains many mucosal commensal bacteria. The udder and vaginal scrapings showed a large amount of diversity.

Conclusions: Gradual changes in gut microbiota were seen with age and indicated a developing microbial ecosystem consistent with previous reports. The unique aspect of this study design and resultant data, is the particular focus on the contribution of colostrum to development of a balanced microbial ecosystem in the gastrointestinal system of the young calf. In future studies this model will be employed to examine the impact of various colostrum handling and management strategies on the developing microbiome.

YS1-048-004

Associations and agreement between deep nasopharyngeal swab and non-endoscopic bronchoalveolar lavage bacterial culture results in preweaned calves

Laura Van Driessche ^{1,*}, Bonnie R. Valgaeren ¹, Linde Gille ¹, Filip Boyen ², Richard Ducatelle ², Freddy Haesebrouck ², Piet Deprez ¹, Bart Pardon ¹

¹Departement of Internal Medicine and Clinical Biology of Large Animals, ²Department of Pathology, Bacteriology and Avian Diseases, Faculty of Veterinary Medicine/ Ghent University, Ghent, Belgium

Objectives: A broncho-alveolar lavage (BAL), performed with a BAL-catheter without endoscopic guidance, is a practically achievable alternative to sample the deep airways in a large number of calves in a limited time frame. Sample quality and agreement with deep nasopharyngeal swab (DNS cultures) are unknown.

Therefore, the objective of the present study was to determine isolation rates of respiratory bacteria, agreement and associations between DNS and BAL samples.

Materials and Methods: A cross-sectional study was performed on preweaned calves with bovine respiratory disease (BRD) (n= 144) from 11 commercial herds (2 veal, 9 beef). DNS and BAL samples were taken from each calf and cultured to detect Pasteurellaceae and Mycoplasma spp.. Culture results were differentiated in a negative culture, polymicrobial culture, pure culture and a dominant culture. Isolation rates between DNS and BAL samples were determined by the McNemar chi-square test for correlated proportions. Agreement and associations between DNS and BAL samples were determined by kappa statistics and logistic regression.

Results: Isolation rates of all studied respiratory bacteria were not different between DNS and BAL samples, with the exception of *Histophilus somni* which was more likely to be isolated from BAL samples (P=0.01). BAL samples were less polymicrobial (P<0.001), more negative (P<0.001) and yielded more pure cultures compared to DNS (P<0.001). Agreement between DNS and BAL was poor for *H. somni* (κ : 0.16) and moderate for the other bacteria (κ : 0.48-0.58). A polymicrobial DNS did not increase the probability of a polymicrobial BAL result, but decreased the probability of isolating a pure culture from the BAL sample for *Mannheimia haemolytica* (P= 0.03) and *Pasteurella multocida* (P< 0.01), except for Mycoplasmata.

Conclusions: In conclusion, BAL samples taken without endoscope are less contaminated compared to DNS, which facilitates interpretation by both bacteriologist and clinicians. The discrepancy between the polymicrobial nature from the DNS compared to the pure culture or negative results from BAL in the same animal suggests that BAL catheter contamination by nasal and pharyngeal passage is less massive than previously believed.

YS1-048-005

The effect of Bovine Respiratory Disease on the Average Daily Gain of Calves in Finland

Vera Haapala ^{1,*}, Tuomas Herva ², Toomas Orro ³, Timo Soveri ⁴

¹Veterinary Medicine, University of Helsinki, Helsinki, ²Atria Plc, Oulu, Finland, ³Veterinary Medicine and Animal Sciences, Estonian University of Life Sciences, Tartu, Estonia, ⁴Veterinary Medicine, University of Helsinki, Helsinki, Finland

Objectives: Bovine respiratory disease (BRD) is a common disease of calves causing economical losses and affecting animal welfare. In Finland BRD seem to have increased as the herd size and calf rearing units have increased. The objective of this research was to calculate the effect of BRD on the average daily gain of calves in Finland.

Materials and Methods: Medication data was collected from five calf rearing units in Finland. The study population was a convenience sample, criteria used to choose the farms were: farms were partners for slaughterhouse Atria, farms had similar infrastructure, the amount of medication used (two farms reported considerable and three farms slight medication) and willingness to participate.

Medication history was collected from 21 groups (3-6 groups per farm) in the year 2010. Calves were categorized to be either healthy, BRD, BRD with another disease or have only another disease. In addition, the frequency of antibiotic treatment for BRD was documented. Only data of the animals that survived until slaughter were included in the study. The final study population was 1031 calves: 358 healthy, 460 with BRD, 98 with other disease and 115 with BRD and another disease. 456 calves had not been given antibiotics, 385 calves had one antibiotic treatment, 190 calves two or more treatments. The length of one antibiotic treatment varied between 1-4 days. Weight was measured at the time of transfer to the finishing unit (mean age of 158 days, 5.3 mo.) and at the slaughter (mean age 584 days, 19.5 mo.).

The effect of other clinical diagnose than BRD, gender, breed, age and square term of age will be studied in a linear random model. Farm and patch of rearing calves will be included as random factors.

Mycoplasma bovis was first diagnosed in Finland in December 2012. At the time of the collected data (2010), it is assumed that BRD was caused by other pathogens than *M.bovis*.

Results: Average estimated daily live weight gain for healthy bull calves was 1040 g at the transfer. Estimated daily carcass gain was 547 g at the slaughter ($n = 307$). On the transfer, the average estimated daily live weight gain of calves that were not treated for BRD was 59 g (95% CI 31-86) more than the gain of calves that were treated twice or more with antibiotics ($p = 0.000$) and 24 g (95% CI 3-45) more than the gain of calves that were treated once ($p = 0.024$). The calves treated twice or more with antibiotics for BRD had 35 g (95% CI 12-58) less daily live weight gain than the ones treated once ($p = 0.003$). There was no interaction effect to the weight gain between antibiotics treatment for BRD and some other clinical diagnosis.

The average daily gain had no longer significant difference at the time of slaughter when comparing animals with treatment and no treatment for BRD.

Conclusions: Calves that have BRD and get at least two antibiotic treatments are clearly affected and their average estimated daily live weight is significantly lower at the time of transfer to the finishing unit. Animals treated only once had also lower average estimated daily live weight but it was less affected. By the time of slaughter there was no longer significant difference. Animals with previous antibiotic treatments for BRD, catch up during the finishing period and do not increase economical loss by lesser weight of the animals at slaughter.

YS1-048-006

Use of available national data to characterise calf survival in Irish dairy herds.

Shane McGettrick ¹, *Máire McElroy ¹Rónan O'Neill ¹Giannis Morfis ²Barry McIntyre ²John Moriarty ¹

¹Central Veterinary Research Laboratory, Department of Agriculture Food and Marine, Celbridge, Co. Kildare, ²Presidion, Dublin, Ireland

Objectives: The Department of Agriculture, Food and the Marine (DAFM) maintains cattle traceability records on Animal Identification and Movement System (AIM). Irish dairy herds rely on replacement calves to provide the foundation of future productivity yet a high proportion of calves die on-farm in early life. The objectives of this study were to use AIM data to (1) determine mortality rates for calves based on herd of origin, (2) categorise herds based on calves born reaching age milestones (3) identify key risk factors present on AIM associated with calf survival and (4) assess potential of AIM data to generate a predictive model for calf survival.

Materials and Methods: Data relating to all calves born to dairy breed dams in 2013 and 2014 and respective herds of origin were identified on AIM and subjected to univariate and multivariate analysis. Specific calf level information included in the analysis was; date of birth, herd of birth, sex, breed, dam parity, movement history, date of death, age at death, disposal location. Specific herd level information included in the analysis was; herd location, total herd size, number of dairy cows in herd. Dairy herd expansion or contraction was determined by identifying changes in total cattle and dairy cow numbers in the years 2013, 2014 and 2015. Individual mortality rates (MR) were generated for all Irish dairy herds in 2013/14 by comparing total calves born to on-farm deaths and were grouped according to age at death (survival period) and geographical location of herd of origin. Herds were categorised according to life expectancy of calves born into a herd. Categories used to group herds for each survival period were high mortality ($MR > 12\%$), medium mortality ($6\% < MR < 12\%$) and low mortality ($MR < 6\%$). A data modelling logistic regression to identify risk factors that influence life expectancy of calves for three survival periods (0-21 days, 21-183 days, >183 days), as well as the impact and the effect of each factor into these pre-defined periods.

Results: The dataset examined comprised of 3,186,589 male and female calves born in 27,145 dairy herds. Birth pattern and mortality pattern was seasonal with 70.5% of deaths in calves born occurring in the first quarter. Mortality rates for age groups 0-21 days, 22-42 days, 43-92 days, 93-183 days and greater than 183 days were 3.92% (124971 calves), 0.85% (27119 calves), 0.78% (24755 calves), 1.01% (32120 calves) and 1.14% (36236 calves) respectively. Average on-farm deaths across all 26 Irish counties for all calves born for the duration of the data period examined was 10.55% in 2013 and 8.23% in 2014 respectively with a with a range of 6.61% to 13.97%.

13.8 % of herds nationally had a mortality rate in excess of 6% in calves under 3 weeks old. 745 herds (representing 2.7% of all herds and 2% of expanded herds) were identified with mortality rates in excess of 12% for 0-21 days category and a further 736 herds were in excess of 12% mortality for calves 21-183 days. Data modelling identified dam parity, calf sex, total number of farm to farm movements, total number of movements through a mart, total herd size, dairy herd size, breed, and date of birth as factors associated with calf survival ($P < 0.05$). Geographical location of herd was not identified as significant. Predictive value of the model was low as factors identified were only able to explain approximately 15% of data variability and are subject to bias and data quality considerations.

Conclusions: Mortality rates for dairy calves based on herd of origin were identified. Mixing of calves from multiple sources into herds in an era of herd expansion may mask a "herd of origin effect" unless analysis of this type is performed. High mortality rates indicate weaknesses in calf production systems within certain herds. The model generated provides proof of concept that data of this type has a value in development of methods to predict calf survivability and identify

factors associated with calf survival. The predictive value of the model was low due to data limitations but inclusion of further data streams may increase predictive power.

YS2-049-001

Development of a diagnostic tool predictive of the ability of newborn beef calves to consume colostrum within 4 hours

Elizabeth R. Homerosky¹,*Edouard Timsit¹Edmond A. Pajor¹John P. Kastelic¹M. Claire Windeyer¹

¹Department of Production Animal Health, University of Calgary Faculty of Veterinary Medicine, Calgary, Canada

Objectives: Newborn beef calf vigour is essential, as it helps ensure timely and adequate colostrum consumption required for successful transfer of passive immunity. Acidosis and asphyxia, often associated with dystocia, can negatively affect vigour. Unfortunately, Apgar scores designed to identify compromised calves are not widely adopted due to impracticality, inconsistent associations with underlying physiology, and unclear recommendations for intervention. Therefore, the objective was to develop a producer-friendly diagnostic tool predictive of a newborn calf's ability to consume colostrum in a timely manner.

Materials and Methods: Data were collected from 77 dystocic and non-dystocic calves born on a large commercial cow-calf operation in Alberta, Canada (Spring of 2014). Following birth, all calves were placed in individual maternity pens with their dams and monitored for 4 h. Calves failing to consume colostrum on their own within 4 h after calving were assisted in colostrum consumption. Blood parameters collected at birth were compared between calves that successfully sucked on their own before 4 h versus those that required assistance to consume colostrum. Multivariable logistic regression using backward stepwise selection was performed to determine associations of calving characteristics and physical examination parameters with the calf's ability to consume colostrum.

Results: The proportion of calves that sucked on their own before 4 h for unassisted, easy assists and difficult assists were 86, 61 and 36%, respectively. Calves failing to suck on their own had lower pH, HCO₃⁻ and base excess and higher lactate compared to their cohorts (P<0.05). Calving ease along with strength of suckle reflex, reaction to tongue pinch, mucous membrane colour, and ambient temperature were predictors of a calf's ability to suck on their own before 4 h (P<0.01). As a diagnostic tool for identifying calves unlikely to suck on their own, calving ease offered the highest sensitivity (89%) whereas suckle reflex had high specificity (98%). Suckle reflex alone was the most accurate method of predicting ability to consume colostrum (P<0.0001), as calves with a weak suckle reflex were 41.6 times less likely to suck on their own as compared to calves with a strong suckle reflex.

Conclusions: Measuring suckle reflex (weak versus strong) at birth is a quick, easy, and simple test that can be performed by producers to assess overall vigour of newborn beef calves. Calves with a weak suckle reflex should be assisted in delivery of colostrum, as suckle reflex was an excellent predictor of inability to consume colostrum in a timely manner. In addition, utilizing calving ease in parallel with suckle reflex may further improve the ability to predict calves unlikely to consume colostrum without assistance.

YS2-049-002

Associations between lung consolidation, bovine respiratory disease treatment and live-weight in UK veal cattle.

P. Williams¹,*T. Potter²R. L. Cooper³

¹MSD Animal Health, Milton Keynes, ²Westpoint Farm Vets, Warnham, ³Rural Enterprise Centre, Penrith, United Kingdom

Objectives: Estimates of bovine respiratory disease (BRD) prevalence on individual farms are usually based on mortality and morbidity (expressed as number of animals treated) data. However this relies on the accuracy of identification of clinical disease and will not include animals with subclinical disease. Examination of lungs at slaughter, combined with treatment records for BRD should provide a better estimate of the true prevalence.

The aim of this study was to examine the prevalence of lung consolidation in UK veal cattle at slaughter and the impact on live-weight at 6 months of age, and associations with treatments for BRD.

Materials and Methods: A total of 189 veal cattle aged between 177 and 240 days from two farms in the UK were examined at a commercial abattoir for evidence of lung lesions. Both farms utilised the same multivalent BRD vaccine protocol and had identical veterinary agreed treatment protocols for BRD.

Lungs were inspected on the slaughter line by the same investigator throughout the study period, using a combination of visual inspection and palpation to detect any tissue consolidation. The left and right cranial, cardiac and diaphragmatic lobes were scored individually as follows: 0: no consolidation in lobe, 1: up to 50% lobe consolidated, and 2: greater than 50% lobe consolidated. Because a lung was divided in 6 different lobes, the maximum total lung consolidation score was 6 x 2= 12. Animals were classified by total lung score: Normal/mild (score 0-1), Moderate (score 2-4) and Severe (score ≥5).

For each animal kill, information was collected from abattoir computerised records: official ear tag number, date of birth, producer name, net weight and carcass grade. Individual animal treatment history was collected from producer records: official ear tag number, treatment date and treatment reason. At the time of lung scoring, the study investigator was blinded to both kill and treatment data, but knew the producer's identity.

To account for variation in dead-weight due to variable age at slaughter, an estimated live-weight at 182 days was calculated from age and weight at admission to the units, live-weight at slaughter (assumed killing-out percentage of 52%) and age at slaughter.

Results: Mean estimated weight at 182 days was 221.2kg (sd=40.2kg).

130 out of 189 (68.8%) animals were identified as having at least one lung lobe up to 50% consolidated. There were 122 animals (64.6%) classified as having a Normal/mild lung score, 48 (25.4%) classified as Moderate and 19 (10.1%) as Severe.

Animals with Normal/mild lung scores had significantly higher (p<0.001) estimated mean weight at 182 days (230kg) than those with Moderate lung scores (203.1kg) and those with Severe lung scores (178kg).

Of all cattle, 42 (22.2%) received at least one treatment for BRD, with 15 (7.9%) receiving two or more treatments. In a linear regression model incorporating BRD treatment, age at arrival, weight at arrival and unit, animals with BRD were 16.4kg lighter (p=0.012) at 182 days.

Animals with Moderate scores had 2.63 times the odds (p=0.016) of having had a BRD treatment than those classed as Normal/mild. Animals classed as Severe scores had 5.20 times the odds (p=0.002) of having had a BRD treatment than those classed as Normal/mild.

Of the 48 animals with Moderate lung lesions, 33 (68.8%) had not received a BRD treatment; of the 19 Severe, 10 (52.6%) had not received treatment.

Conclusions: Both BRD treatment and lung consolidation were associated with a biologically significant lower live-weight at 182 days (six months)

Around two thirds of animals showed some lung consolidation at slaughter, yet only around a quarter were previously treated for BRD. This suggests that either the farmer chose not to treat certain animals with BRD or, as is more likely to be the case, the disease was not detected or was subclinical.

Comments: This study highlights the economic impact of reduced performance due to lung damage and that the current method of on-farm disease detection underestimates the true disease prevalence. The wider training of farmers in the use of BRD scoring systems, such as the Wisconsin Calf Health Score, may improve disease detection rates. New automated disease detection systems, based on changes in animal behaviour and the presence of pyrexia, should be evaluated as a potential tool for improved diagnostic sensitivity.

YS2-049-003

On farm monitoring of the four Q's of colostrum management is important.

K. Hart¹, *P. Williams² David Barrett³ Kristen Reyher³

¹George Farm Vets, Malmesbury, ²MSD Animal Health, Milton Keynes, ³School of Veterinary Science, University of Bristol, Bristol, United Kingdom

Objectives: Colostrum management is crucial to provide calves with passive transfer of immunity, as calves are born agammaglobulinemic. Failure to ingest sufficient quantities of good quality colostrum is a major risk factor leading to mortality and morbidity in neonatal calves in the UK.

The objective of the study was to assess the colostrum management on 6 commercial dairy farms in the UK. All four Q's (Quantity, Quickly, Quality, and sQueaky clean) were assessed and compared to target measures.

Materials and Methods: A total of 206 colostrum samples were collected from cows and heifers from six UK dairy herds in the Wiltshire and Gloucestershire area, between April and July 2013. Herds were recruited due to their interest in calf management. Both volume of colostrum, and the time colostrum was fed to calves were recorded. Each farm was asked to collect a sample of colostrum at the point which the colostrum entered the calf (e.g. out of the oesophageal feeding tube) into a sterile milk sample pot provided, and to label appropriately. Samples were stored between 4-8°C for a maximum of 48 hours before submission. At the practice laboratory, samples were assessed for quality by the same operator using a Brix refractometer, a reliable method of estimating IgG content. Samples were also cultured for 24 hours to count colony forming units (cfu) /ml, to determine the bacterial load.

Results: The mean volume of first colostrum given on farms was 3.6 litres, ranging from 2.0 – 4.0 litres. Only 57% (117/206) of calves received the target 4L of colostrum as an initial feed.

The mean calving- colostrum administration interval was 5.4 hours with considerable variation between farms, with farm 2 mean time being 3.4 hours compared to farm 5 being 6.7 hours. Since more samples were collected from farms 1 and 2, the majority of calves (57% 118/206) received colostrum within the target 4 hours of birth.

The mean value for colostrum quality, as measured by percentage Brix (%Brix), was 23% and ranged from 14-31%. Only 40% (82/206) colostrum samples had a %Brix value above the target 22%, which equates to 50g/dL IgG. There was a large variation both within and between farms. In samples where the source was known (n=80), there was a significant difference between heifer and cow colostrum, with heifers' mean value being 21.8% (SD 0.6), compared to 23.7% (SD 0.6) for cows (P=0.02 using a two-sample t-test with equal variance).

The mean bacterial count was 129,391cfu/ml. The target bacterial count is less than 50,000cfu/ml, and counts over 250,000cfu/ml have been linked to fatal enterotoxaemia. Only 17% (29/175) samples were below target (50,000cfu/ml) and 9% were above 250,000cfu/ml. There was considerable variation between farms as well as within farm results. Farm 1 had the highest mean bacterial count at 230,039cfu/ml, ranging from 98,000cfu/ml to 831,000cfu/ml. Farm 3 had the lowest mean bacterial count at 84,393cfu/ml ranging from 10,000 to 295,000cfu/ml.

Conclusions: Less than two thirds of calves received either adequate volume of colostrum or received it within adequate time frame. Other concerns are colostrum quality and bacterial load. Colostrum quality was below the target %Brix value in 40% of samples, indicating a low level of IgG. Very few farms currently monitor colostrum quality and then adjust volume fed accordingly. Measurement of colostrum cleanliness is not routinely undertaken in the UK. The high bacterial load in many colostrum samples in this study indicates colostrum cleanliness should be assessed as part of any investigation into colostrum management.

Comments: This study highlights the importance of including on-farm monitoring of colostrum management, and assessing all four Q's. As the farms selected had been chosen for their interest in calf management, it is possible that results for the national herd could be worse. Where targets are not being met, intervention measures can then be implemented to help reduce the risk of disease in neonatal calves.

YS2-049-004

Effects of dietary forage on rumen pH and bacterial community in Holstein calves during weaning transition.

Yohan Kim¹, *Natsuki Ohtani² Yu-mi Watanabe² Keiji Okada¹ Shigeru Sato^{1,2}

¹United Graduate School of Veterinary Science, Gifu University, Gifu 501-1193, ²Cooperative Department of Veterinary Medicine, Iwate University, Morioka 020-8550, Japan

Objectives: Excessive intake of rapidly fermentable carbohydrate causes rumen acidosis, and disturbs the normal flora of rumen. Although several studies have attempted to investigate the effect of feeding material on rumen environment, the relevance between ruminal pH and microbiota during weaning transition still remains unclear. Therefore, the objective of this study was to investigate the relationship between ruminal pH and bacterial communities when feeding the calf starter with or without forage to dairy calves during weaning transition.

Materials and Methods: Sixteen rumen cannulated Holstein bull calves were raised using milk replacer (24% CP and 20% fat), calf starter (22% CP and 3% fat) and alfafa hay. Calves were randomly assigned into calves fed calf starter with forage (HAY, n=8) and only a calf starter (CON, n=8). Ruminal pH was measured continuously in every 10 min by radio transmission pH measurement system during the experiment. Ruminal fluid samples for VFA analysis and total bacterial DNA extraction were

collected from the ventral sac of the rumen, the morning prior to feeding at -1, 0, 1, and 3 weeks after the weaning. Ruminal bacterial composition and the copy number of 16S rRNA of bacterial species were analyzed by 454 pyrosequencing and quantitative real-time PCR, respectively.

Results: 24-h mean pH of rumen was affected by diet, and HAY group had higher ruminal pH when compared with CON group ($P < 0.001$). The ratio of ruminal acetate to propionate were significantly increased ($P < 0.05$), and a tendency towards increased ruminal propionate level was observed ($P = 0.0849$) in the CON group. There were significant differences between HAY and CON group in propionate level ($P < 0.05$) at 1 week and the ratio of ruminal acetate to propionate at 1 ($P < 0.01$) and 3 ($P < 0.01$) weeks. By the 454 pyrosequencing, HAY group presented significantly higher bacterial richness in Chao1 ($P < 0.05$) and ACE ($P < 0.05$), and Shannon index indicated that HAY group had a tendency ($P = 0.0529$) to have higher bacterial diversity than the CON group. When compared with CON group, there were significant differences in the relative abundances of phyla (Bacteroidetes; $P < 0.05$ and Actinobacteria; $P < 0.05$) and genus (Prevotella; $P < 0.05$) in HAY group. By the qPCR, HAY group was affected by diet in the copy number of *Ruminococcus albus* ($P < 0.05$) and *Ruminococcus flavefaciens* ($P = 0.0872$), and there were also significant changes in the copy number of total methanogen ($P < 0.05$) and *Megasphaera elsdenii* ($P < 0.01$) over time. When compared with CON group, the copy number of *R. flavefaciens* ($P < 0.05$) and *R. albus* ($P < 0.05$) were significantly increased at 1 and 3 weeks in HAY group, respectively.

Conclusions: Calves fed calf starter with forage had significantly higher 24-h mean ruminal pH when compared with calves fed only a calf starter. The relative abundances of Bacteroidetes, Actinobacteria, and Prevotella were significantly affected by diet and the copy number of 16S rRNA of cellulolytic bacteria, such as *R. albus* and *R. flavefaciens*, were significantly increased in HAY group. Therefore, forage and calf starter feeding to calves is related to ruminal pH and bacterial communities, and may affect the establishment of fermentative ruminal functions during weaning transition.

YS2-049-005

Prevalence, associated clinical conditions and prognostic relevance of hypoglycaemia in 7,000 hospitalized neonatal calves

Florian Trefz¹, *Melanie Feist¹, Ingrid Lorenz²

¹Clinic for Ruminants with Ambulatory and Herd Health Services, LMU Munich, Oberschleißheim, ²Tiergesundheitsdienst Bayern e.V., Poing, Germany

Objectives: Hypoglycaemia is known to occur as concomitant of neonatal diarrhoea and experimentally induced endotoxaemia in calves. However, the relevance of this metabolic imbalance in spontaneously diseased calves has been poorly investigated. The objectives of the present study were therefore to determine the prevalence of hypoglycaemia in a large population of hospitalized neonatal calves, to identify the underlying health problems that are associated with this condition, to assess the clinical predictability of hypoglycaemia and finally to analyse the possible impact on prognosis.

Materials and Methods: For the purpose of this study, the data of 7,000 neonatal calves (up to 21 days of age) admitted to the Clinic for Ruminants with Ambulatory and Herd Health Services, LMU Munich, between October 1997 and March 2008 were retrospectively analyzed. Clinical findings of a subset of 100 calves with severe hypoglycaemia

(plasma glucose concentration < 2 mmol/L) were extracted from the medical records and compared to those of 100 randomly selected calves with plasma glucose concentrations in the reference range (4.4 to 6.9 mmol/L). Plasma glucose concentrations were determined on admission to the hospital and survival was defined as discharge from the hospital.

Results: The prevalence of severe hypoglycaemia was 6.0%. In those calves the survival rate was 18.8%, which was poor opposed to 75.6% discharged animals in the group of calves with initial plasma glucose concentration in the reference range. The overall recovery rate was 66.8%. A binary logistic regression analysis indicated that in calves with a plasma glucose concentration of < 7 mmol/L the odds for non-survival increased by 57.5% for every mmol/L decrease of plasma glucose concentration.

Review of the medical records revealed that severe hypoglycaemia was significantly associated ($P < 0.001$) with clinical and/or post-mortem evidence of septicaemia, generalized peritonitis of varied origin, severe hypothermia and a history or clinical diagnosis of severe malnutrition. However, the proportion of calves with signs of central nervous involvement like seizures and opisthotonus was not significantly different between calves with severe hypoglycaemia and calves with normoglycaemia.

Conclusions: Hypoglycaemia in hospitalized neonatal calves is of rare occurrence, but is associated with serious health problems and therefore represents a reliable indicator of non-survival. We concluded that hypoglycaemia should be suspected in neonatal calves with an abdominal emergency, clinical evidence of septicaemia and a history or signs of malnutrition. However, a hypoglycaemic state can only be suspected clinically, indicating that low-cost, reliable and rapid on-farm test-methods would represent a helpful tool in critically ill neonatal calves.

A New Obstetric Tool: Can GYNstick Really Make A Difference? - Survey Among Bovine Practitioners

Franz Schleederer¹·Axel Wehrend²¹Private Practice, Andorf, Austria, ²Gynecology and Obstetrics, Vet med University Giessen, Giessen, Germany

Objectives: Dystocia in cattle affects up to 50% of primiparous and 30% of adult cows¹. Obstetrics are crucial in order to reduce stillbirth rates. GYNstick^{2,3,4}, a new tool for treating dystocia, has been available for practitioners for almost 3 years. Nearly 400 vets in Germany and Austria are currently practising with this obstetrical instrument in their daily practice, and approximately 2000 vets are using it worldwide. A survey was conducted among 49 German and 5 Austrian practitioners to obtain feedback about their experience with this instrument and their recommendations for its use.

Materials and Methods: 54 veterinarians responded to an online questionnaire (Monkey Survey) initiated by the Faculty for Veterinary Medicine of the University of Giessen. Veterinarians were chosen based on their practical experience with this new instrument for at least 1 year. The data analysis (SPSS Version 22; IBM inc) compared the veterinarians experiences by gender, age and frequency of dystocia interventions. The participants have been identified by hazard out of a data sets of GYNstick distributors. 196 users have been invited to reply, 54 responded finally and completed the questionnaire (27,55 %).

Results: Most of the practitioners (64%) stated that GYNstick was recommended to them by another colleague. The geometrical mean of dystocia cases per week was 1.52 (female, 1.44 vs. male, 1.63; p=0.206; t-test). For 83 % of the responders, the correction of a twisted uterus was the most frequent indication for using the instrument prior to other indications like correction of malpositionings or reach of displaced extremities.

Most veterinarians (92.5 %) think that the instrument reduces the duration of dystocia, without differences between males and females (p=0.9, X²). Forty-three percent of the vets estimated a 30% time reduction. Forty-four percent estimated a 30 - 50% time reduction. Approximately 2/3 (65 %) of the vets felt that the instrument did not impact the number of live calves born. For the remaining veterinarians, 24% thought that number of calves born alive was 30% greater after implementing this tool. Nine percent of veterinarians estimated an increase in live calves of 50% (no gender differences; p=0.1, X²).

84% of the practitioners are convinced that the instrument is a more effective life-saver than traditional obstetrical instruments.

All users are convinced that it is less exhausting in comparison to other tools or manual interventions. In addition, 21% said that muscle efforts are reduced by 50-80%. Interestingly, this outcome was not impacted by sex of the veterinarian (p=0.1, X²).

All respondents replied that they would recommend (81% full agreement, 19%, recommend if asked) the tool to their colleagues.

Conclusions: A new obstetrical instrument, the GYNstick, was well accepted among veterinary practitioners in Germany and Austria. Most users were female and graduated in the last 14 years. All respondents would recommend it to their colleagues. Veterinarians should consider using this tool to reduce the physical impact of difficult calvings to newborn calves and their dams. And finally it makes life easier for vets as well - in a gender changing bovine vets world really an important and actual aspect.

Prevalence of gross pathological lesions indicative of traumotocia in stillborn calves in Polish dairy herds

Dawid Król¹·Paulina Jawor¹·John F. Mee²·Edyta Żyromska¹·Wojciech Nowacki¹·Tadeusz Stefaniak¹¹Department of Immunology, Pathophysiology and Veterinary Preventive Medicine, Wrocław University of Environmental and Life Sciences, Poland, Wrocław, Poland, ²Animal and Bioscience Research Department, Teagasc, Moorepark Research Centre, Fermoy, Ireland

Objectives: Dystocia is the most common cause of perinatal calf mortality. Disproportion between pelvic size and the size of the calf, fetal malposition and inappropriate calving assistance may lead to trauma and fetal death. Evidence of inappropriate calving assistance and associated trauma can be detected during post mortem examination. If inappropriate calving assistance resulting in trauma is the main cause of death this is defined as traumotocia.

Materials and Methods: The study was carried out on 121 stillborn (SB) calves born dead after a gestation period of ≥ 260 days or died within 6 hours of birth, from November 2013 to June 2015 in 30 Polish Holstein-Friesian herds (1-1,031cows/herd; 1-35 SB/herd). Data were recorded on calving assistance, fetal position and the time of death after birth for calves which were born alive. All calves were subjected to a complete laboratory necropsy within 12 hours after calving, and in the calves which were born alive, after death. Each carcass was examined by the same protocol. Lesions of trauma were recorded, categorized and their contribution in the cause of death was ranked. Calves with traumotocia were assigned to one of five mutually exclusive groups according to the extent/severity and type of trauma: (1) blood vessel rupture leading to extensive internal haemorrhage, (2) spine fracture with associated hematoma, (3) large ($\geq 10\text{cm}^2$) diaphragm tear, (4) multiple (≥ 3) ribs fractures with associated haematoma and (5) other causes.

Results: Of the 121 calvings (28 calves from twin calvings), 114 (94%) were observed [of which 111 (92%) were assisted and 3 were observed/unassisted] and seven (6%) were unobserved. Of the 111 assisted cases (75 with calving jack), 24 (22%, singleton calvings) had lesions associated with traumotocia. In six cases blood vessel rupture [vena cava caudalis (4 calves), vena cava cranialis (1 calf) and diaphragm vessels (1 calf)] was associated with extensive haemorrhage into the abdominal cavity (2 cases), thoracic cavity (3 cases), and both cavities (1 case). Spine fracture with associated haematoma was observed in three calves (Salter-Harris type I spine fracture at the thoraco-lumbar or L₁-L₂ junction). In two calves there was a large diaphragmatic tear. Fracture of the ribs with associated haemorrhage was the most commonly observed traumotocic pathology (12 cases). Such fractures were most commonly located at the costochondral junction (8 cases). In one case extensive occipital trauma including haemorrhage was detected (associated with a calf falling on its head on to a concrete floor). In addition to these lethal lesions, there were associated sublethal lesions of traumotocia in the majority of these calves.

Conclusions: This study showed that in these Polish dairy herds approximately one fifth of stillbirths were caused by traumotocia; half of these were caused by fractured ribs. These findings have implications for veterinary education of farm personnel in when to assist and how to use mechanical calving aids when assisting difficult calvings.

Abortion/Stillbirth Investigation

P04-004-003

Diagnosis of Neospora and Leptospira in bovine abortions/stillbirths – how does foetal serology compare with tissue qPCR testing?

John F. Mee¹·Cosme Sánchez-Miguel²·Mikhail Nosov³·John Gilmore³

¹Animal and Bioscience Research Department, Teagasc, Fermoy, ²Cork Regional Veterinary Laboratory, DAFM, Cork, ³Molecular Diagnostics, FarmLab Diagnostics, Elphin, Ireland

Objectives: Neospora caninum and Leptospira Hardjo were detected in 4.2 and 7.4% of Irish bovine fetuses (2013), respectively. As diagnosis of both relies mainly on foetal serology, under-diagnosis is likely. In only approximately a third of abortion cases is a cause diagnosed. Recently, validated quantitative real time PCR tests have been developed for these foetopathogens (FarmLab Diagnostics). By combining foetal serology and qPCR it may be possible to address the issue of under-diagnosis. Hence, the objective of this study was to compare the infection detection rate of serology and molecular diagnostics in the same aborted/stillborn fetuses.

Materials and Methods: Foetal blood/transudate, kidney and brain samples were collected from 141 aborted fetuses and perinates (138 were tested for Neospora and 141 for Leptospira) in 36 dairy herds in the main dairying region of Ireland (Munster), (1-12 fetuses/herd) between January and June, 2015. None of the perinates had consumed colostrum. Neospora serology was conducted using an IgG ELISA (IDEXX Bovine Serum Neospora Caninum, IDEXX, Bern, Switzerland, (sensitivity of 95.8% and a specificity of 100%) with results reported as negative (<30% optical density, OD), inconclusive (30-40% OD) or positive (>40% OD). Leptospira serology was conducted using an ELISA (PrioCHECK L. hardjo Ab, Prionics, Zurich, Switzerland) which detected anti Leptospira hardjo IgG (sensitivity of 99% and specificity of 85%). The results are reported as negative (<40% OD), inconclusive (40-60% OD) or positive (>60% OD). Both tests were run in the Cork Regional Veterinary Laboratory. Following gDNA extraction of kidney (for Leptospira) and brain tissue (for Neospora), purified samples were tested by real-time PCR with the target-specific TaqMan primers. Both qPCRs were run in FarmLab Diagnostics Laboratory.

Results: In total 26 (18.8%) fetuses were either Neospora ELISA or qPCR test-positive; 8 (5.8%) and 18 (13%) Neospora ELISA and qPCR test-positive, respectively. Of 8 Neospora ELISA test-positives, 2 (25%) were Neospora qPCR test-positive. Of 18 Neospora qPCR test-positives, 2 (11.1%) were Neospora ELISA test-positive. In total, 2 (1.5%) fetuses were both Neospora ELISA and qPCR test-positive. Neospora ELISA and qPCR test-positives were detected in 6 (17.1%) and 11 (30.5%) herds, respectively. In total 26 (18.4%) fetuses were either Leptospira ELISA or qPCR test-positive; 0 and 26 (18.4%) Leptospira ELISA and qPCR test-positive, respectively. Of 0 Leptospira ELISA test-positives, 0 were Leptospira qPCR test-positive. Of 26 Leptospira qPCR test-positives, 0 were Leptospira ELISA test-positive. In total, 0 fetuses were both Leptospira ELISA and qPCR test-positive. Leptospira ELISA and qPCR test-positives were detected in 0 and 17 (47.2%) herds, respectively. Of 26 Leptospira qPCR test-positive fetuses, 2 (7.7%) were also Neospora qPCR test-positive and of 18 Neospora qPCR test-positive fetuses, 2 (11.1%) were also Leptospira qPCR test-positive. Both cases of co-infection were from the same herd.

Conclusions: It is concluded that these preliminary data indicate a much higher foetal infection detection rate with qPCR compared to foetal serology, particularly for pathogenic Leptospira. There was poor agreement between fetal serology results and qPCR results for both foetopathogens, in particular for pathogenic Leptospira. While it is accepted that foetal infection does not prove cause of death, the higher

detection rate of foetopathogens in these fetuses by qPCR warrants further investigation. It is recommended that more widespread sampling nationally be conducted before extrapolation of these results.

Abortion/Stillbirth Investigation

Potential Nutritional Causes Of Stillbirth In Dairy And Beef Calves

Robert Van Saun^{1*}

¹Department of Veterinary & Biomedical Sciences, Pennsylvania State University, University Park, United States

Objectives: Stillbirth remains a significant reproductive loss to the dairy and beef cattle industries. Dystocia accounts for a large proportion of stillbirths, but at least 30-40% of stillbirths have no definitive diagnosis. The study objective was to identify possible nutrition-related causes of stillbirth in dairy and beef calves.

Materials and Methods: In this study a stillbirth was defined as a calf between 265 days gestation and 6 hours postcalving. Stillborn calves meeting this definition were collected from various dairy and beef cattle farms throughout Pennsylvania. If historical evidence suggested the stillbirth was due to dystocia, then the submission was not included in the study. All eligible stillborn calves underwent a full diagnostic necropsy procedure (gross and histopathology) including measurements of body weight and crown-rump length measurement. Calf gender, haircoat condition, lung insufflation status and any obvious physical abnormalities were noted. Microbiologic evaluations specifically addressing BVD, IBR, leptospirosis and Neospora were completed on all submissions as well as routine microbiologic culture of various tissues. Liver samples were collected and submitted for mineral analysis including calcium, magnesium, cobalt, copper, iron, manganese, selenium and zinc using ICP/MS methodology. Measurement of vitamins A (total retinol) and E (α-tocopherol) concentration were by high pressure liquid chromatography (HPLC). All values were determined on a wet weight (WW) basis and converted to dry weight (DW) based on measured dry matter ratio of liver samples. A section of the thyroid gland was collected for histopathologic evaluation to assess iodine status. Analysis of variance (ANOVA) statistical methods were used to determine potential effects of breed (dairy or beef), gender, season or diagnostic category (infectious, congenital, idiopathic) on mineral and vitamin measures.

Results: To date a total of 27 calves (7 beef; 20 dairy) met the case definition and had all determinations completed. Beef calves were of various breeds, but predominately Angus and dairy calves were predominately Holstein breed. Mean crown-rump length and birth weight was 93.7 ± 9.3 cm and 31.0 ± 8.6 kg for dairy calves and 91.8 ± 8.2 cm and 28.2 ± 7.5 kg for beef calves, respectively. There was one large beef calf (55 kg) and one small dairy calf (16.4 kg) not included in these means. Overall gender distribution was equal, but beef calves were predominately female (71%) whereas dairy calves were more males (60%). No calf had inflated lungs with 69% and 31% with none or partial lung insufflation, respectively. Two (7.4%) calves were considered to have congenital defects, 7 (25.9%) calves had an identified infectious agent and 17 (63%) of cases had no definitive stillbirth diagnosis. Overall there were 1.6 (range: 0-4) mineral deficiencies and 0.8 (range: 0-2) vitamin deficiencies per calf. Total mineral and vitamin abnormalities or deficiencies per calf were 3.1 and 2.4, respectively. Vitamin A deficiency (<8 µg/g DW) was the primary (18/27, 67%) vitamin abnormality. Low hepatic mineral concentrations were seen with cobalt (13/27, 48.1%),

selenium (11/27, 40.7%), manganese (7/27, 25.9%), iron (5/27, 18.5%), copper (2/27, 7.4%) and zinc (3/27, 11.1%). Excessively high iron and zinc concentrations were found in 6 (22.2%) and 11 (40.7%) cases, respectively. Effects of gender, breed and crown-rump length did not influence mineral or vitamin concentrations.

Conclusions: These preliminary data strongly support the role of trace mineral and vitamin deficiencies as potential underlying causes of stillbirth losses in dairy and beef cattle herds. Further study is warranted to confirm these results and identify specific mechanisms possibly related to antioxidant status.

Comments: Research was supported by a Pennsylvania Department of Agriculture grant.

Laboratory findings suggesting an association between BoHV-4 and bovine abortions in southern Belgium

Laurent Deloos¹, Guy Czapllicki¹, Jean-Yves Houtain¹, Fabiana Dal Pozzo², Claude Saegerman²

¹Santé animale, ARSIA asbl, CINEY, ²UREAR, ULg - FMV, Liège, Belgium

Objectives: Abortions cause heavy economic losses for the bovine sector. The use of a standardized panel of analyses covering a large spectrum of pathogens responsible of abortion in cattle, allowed demonstrating the direct involvement of at least one pathogen in 57% of analysed abortions in the southern part of Belgium. This result suggests a margin of improvement in the diagnostic efficacy. In order to evaluate the interest to broaden the list of pathogens included in the panel of analyses, the implication of bovine herpesvirus 4 (BoHV-4) in abortion was assessed by two different studies.

Materials and Methods: Two studies were conducted in the southern part of Belgium, including five different provinces (Walloon Brabant, Hainaut, Namur, Liege and Luxembourg). In the study area, 12,000 cattle herds with 1,257,000 bovines are registered. In the first study, coupled serology was performed after abortion on 714 dams to identify specific seroconversion against BoHV-4. In the second study, the virus ability to infect the foetus was investigated and 368 cases of bovine abortions were specifically tested for BoHV-4, with PCR on foetus tissues and ELISA on dam and foetus sera.

The diagnosis of BoHV-4 in the maternal serum was performed using an indirect ELISA test (Edwards and Newman, 1985; Wellenberg et al., 1999) according to the manufacturer's instructions (BIO K 263/2 ©, BioX Diagnostics, Rochefort, Belgium). Concerning the foetal serology, the same ELISA was performed using a 6 mm disc of saturated blood (Bailey et al., 1967).

Direct diagnosis of BoHV-4 was performed on spleen fragments stored at -20 °C. DNA extraction was performed using KingFisher TM Flex 96 Magnetic Particle Processors (Thermo Scientific TM, UK) and LSI MagVet TM Universal Isolation Kit (Life Technologies, UK) and was followed by BoHV-4 DNA detection using a commercial PCR test (LSI VetMax BoHV-4 © TM, Life Technologies, UK), according to the manufacturer's instructions (Wellenberg et al., 2001). The PCR reactions were performed with a Stratagene Mx3500P (Agilent Technologies, USA). According to the manufacturer's instructions, a sample was considered positive for a threshold cycle (= Ct) value lower than 46.

Results: During the first study, 760 cows out of 1,158 (65.6%; 95% CI: 62.8-68.4%) were seropositive at first sampling. 714 cows were sampled a second time after abortion for a coupled BoHV-4 serology. Based on an increase of at least two orders of magnitude of the S/P ratio between the first and the second sampling, 113 cows were seropositive at the coupled serology against BoHV-4, among the 456 cattle that were seropositive only at first sampling. Out of 258 seronegative cows at the time of abortion, 26 seroconverted at the second sampling, suggesting a correlation with BoHV-4 primary infection.

During this second study, antibodies against BoHV-4 were identified in sera of 279 cows out of 368 cows collected after abortion (75.8%; 95% CI: 71.1-80.1%). The DNA of BoHV-4 was detected by PCR in the spleen of four fetuses (1.1%) and for three of them, no other specific pathogens or opportunistic bacteria could be identified. These four fetuses aged between 6 and 9 months and came from seropositive cows at the time of abortion. However, these four fetuses were all seronegative regarding to BoHV-4. On the contrary, in the foetus where the highest Ct value for BoHV-4 could be measured in the spleen, an opportunistic bacterium (*Trueperella pyogenes*) was isolated from the abomasal fluid. The four PCR-positive samples presented a Ct value varying from 23 to 36. Three BoHV-4 seropositive but PCR-negative fetuses (0.8%) were detected and were derived from seropositive cows. Opportunistic bacteria were isolated on the abomasal fluid of one of these three cases (*E. coli*).

Conclusions: Despite the fact that the role of BoHV-4 as etiologic agent of a specific entity remains a matter of controversy, these two studies showed a high seroconversion for this pathogen in bovine at abortion, the proof of a foetal immunity response and the direct diagnosis of this virus in foetal spleen. These results constitute additional arguments of the possible involvement of BoHV-4 in abortion in the southern part of Belgium.

Abortion/Stillbirth Investigation

P04-004-009

Genomic-based identification of host and environmental *Listeria monocytogenes* strains associated with an abortion outbreak in beef heifers in the US

Katherine J. Whitman¹, James L. Bono², Michael L. Clawson², John D. Loy³, Terrance M. Arthur², Joseph M. Bosilevac², Jeff D. Ondrak¹

¹Great Plains Veterinary Educational Center, University of Nebraska, ²US Meat Animal Research Center, Clay Center, ³Veterinary Diagnostic Center, University of Nebraska, Lincoln, United States

Objectives: *Listeria monocytogenes* (LM) can cause late-term abortions in cattle. In a listerial abortion outbreak, objectives for this diagnostic work-up were to employ novel case and environmental sample collection protocols, then define the probable cause of the outbreak by comparing LM strains isolated from cases and their environment through whole-genome sequencing.

Materials and Methods: Twenty crossbred heifers that aborted from late January into February, 2014, were identified. Presumptive diagnosis of listerial abortion was based on two LM culture positive, late-term aborted fetuses. Proximal vaginal/distal cervical swabs (VCS) or retained fetal membranes (RFM) from heifers were then submitted for LM culture and PCR. Silage sampled via a grid system protocol and water sources were also submitted for culture and PCR. Resulting strains were subjected to whole-genome sequencing and compared.

Results: Heifer submissions identified 16/20 LM positive samples; 10/10 RFM and 6/10 VCS were positive, respectively. 11/45 environmental

samples were positive. Because definitive diagnosis and point-source determination can be challenging, genomic sequencing of case and environmental isolates was performed, demonstrating that 10/18 fetal/heifer samples and all environmental samples were a related strain. Remaining case strains were similar to each other, but genetically distinct from all other case and environmental strains.

Conclusions: When fetal materials are unavailable, VCS and RFM samples are an effective means to diagnose abortions caused by LM. Sampling feed in an organized, documented manner may help identify the source. In this investigation, two LM case strains were identified, one genetically linked to contaminated silage and/or water, while the source of the other strain remains unknown.

Abortion/Stillbirth Investigation

P04-004-010

Veterinarians and farmers' perceptions of abortion in cattle and their barriers and motivators towards abortion investigations

Eva Kenny ¹; Emily Windham ¹; Marnie Brennan ¹; Wendela Wapenaar ¹

¹University of Nottingham, Sutton Bonington, United Kingdom

Objectives: Abortion in cattle reduces production efficiency and causes significant economic loss to dairy and beef farmers. Abortion investigations are pursued in variable frequency by veterinarians and their clients. This may be due to a lack of information or because the diagnostic success rate is poor; even when a foetus and placenta are submitted, the reported diagnostic rate in the UK is still estimated to be 35%.

Materials and Methods: The aim of this study was to gain an understanding of veterinarians' perceptions of cattle abortion on their clients' farms and to determine their barriers and motivators towards abortion investigations. The veterinarians' perceptions were then compared to farmers' perceptions towards cattle abortion investigations, based on data collected in a previous study.

A questionnaire-based survey of 134 British and Irish veterinarians collected information on the perceptions of cattle abortions and determined barriers and motivators of the veterinarians, as well as their perceptions of farmers' barriers and motivators, towards abortion investigations. Results were compared to farmers' barriers and motivators towards cattle abortion investigations, which were collected previously in a similar questionnaire surveying 379 British and Irish cattle farmers.

Results: Veterinarians and farmers had similar perceptions of the definition and estimated incidence of cattle abortion. Veterinarians were mainly deterred from recommending sample submission by lack of good quality samples, low diagnostic rate and cost. Veterinarians and farmers were receptive to help to reduce cattle abortion and many requested an improved laboratory service. The majority of respondents were motivated to recommend sample submission in the presence of a high abortion incidence and felt an incidence higher than 4% warranted investigation. Veterinary respondents overestimated cost and underestimated lack of concern or understanding as barriers for farmers to investigate abortions. Overall, it seemed veterinarians did not expect clients to be prepared to pay as much as farmers were willing to pay for an abortion investigation; three times as many farmers as veterinarians felt that they should pay € 501-1000 for all applicable laboratory analyses. Veterinarians also overestimated cost as a barrier and reduced cost as a motivator to farmers regarding the submission of samples for abortion investigation. Nineteen per cent of veterinary respondents

were deterred from recommending farmers to submit samples due to the cost of investigation. There was a disparity between the percentage of veterinarians recommending abortion investigation (97%) and farmers who actually indicated to submit samples for investigation (51%). Improved communication between veterinarians and farmers may increase uptake of abortion investigations.

Conclusions: The study gained an insight into British and Irish veterinarians' barriers and motivators to, and perceptions of, cattle abortion investigation, as well as their perceptions of farmers' attitudes. Addressing barriers to abortion investigations in cattle, such as improving knowledge transfer and the practicalities of submitting samples, as well as differences between farmers' attitudes and veterinarians' perceptions of farmers' attitudes, may result in improved uptake of abortion investigation services.

Abortion/Stillbirth Investigation

Can veterinary practitioners guesstimate how long a foetus is dead in utero using corneal opacification as a guideline?

John F. Mee ¹; Aine B. Collins ¹

¹Animal and Bioscience Research Department, Teagasc, Fermoy, Ireland

Objectives: Once somatic mortality occurs post-mortem decomposition begins. The rate at which this occurs is dependent upon the cause of death, environmental and body temperature and microbial flora. For foetuses which die in utero it is usually not possible, under field conditions, to know when they died. One indicator which may be of value in estimating the time of death relative to time of birth (intrauterine retention time) is corneal opacity (clouding, blueing). To test this hypothesis a pilot study was conducted using newborn calves.

Materials and Methods: Four eyes from four Holstein-Friesian newborn calves with known time of death were used. Two eyes were enucleated and placed in plastic bags in a water bath at 38.5° for 96 hours (4 days). This was to represent a dead in utero simulation (DIU). The other two eyes were left in situ in the skull and placed in a pen at ambient temperature (January & March), for 168 hours (7 days). This was a control group (C). The gross changes in the eyes were recorded and photo-documented every 12 hours for the DIU and every 24 hours for the C eyes.

Results: The first signs of corneal opacity were visible at 24 and 48 hours in the DIU and C eyes, respectively. The degree of corneal opacity was substantially greater in the DIU compared to the C eyes at 24 and 48 hours, respectively. In addition peri-orbital tissue also showed signs of autolysis in the DIU group at 24 hours but not in the C eyes. Complete corneal opacity was visible at 36 and 96 hours in the DIU and C eyes, respectively. Again the degree of corneal opacification was greater in the DIU than in the C eyes at 36 and 96 hours, respectively. After 48 hours the turgor of the DIU eyes decreased but not in the C eyes. These findings suggest the onset of opacity in DIU eyes is between 12 and 24 hours, considerably earlier than at ambient temperature.

Conclusions: Corneal opacity may be used by veterinary practitioners as an indicator, along with others, of intrauterine retention time after bovine foetal mortality. Pre-partum opacity is not likely to be confused with peri or postpartum opacity in fresh carcasses which are examined within 24 hours of death. However, storing fresh carcasses at 4°C accelerates the onset of corneal opacity (and lens opacity). These results need to be repeated on a larger number of specimens and under varying simulation conditions.

Failure of passive immune transfer in calves: total cost and resources to be allocated for its managementDidier Raboisson¹, Clélia Cahuzac², Pauline Trillat²¹INP-ENVT INRA-IHAP, ²Toulouse Veterinary School, Toulouse, France

Objectives: Colostrum intake is reported as a key factor for the newborn calf health. Failure of passive immune transfer (FIT) is linked to no or low colostrum intake and is defined as low plasma IgG or total proteins at 24 - 48 hours of age. FIT is associated with an increased risk of mortality and morbidity. In spite FIT stakes are consensual, no economic assessment has been performed up to now. This work aims to (i) estimate the total cost of FIT, and to (ii) define the resources to be allocated to FIT, in the French context.

Materials and Methods: The total cost of FIT was calculated thanks to a stochastic two-step economic method. A meta-analysis (package Metafor, R) was firstly performed to clarify the adjusted links between FIT and morbidity or mortality. A dataset was drawn with the models of peer-reviewed papers reporting the odd-ratios (OR) of mortality or morbidity for calves with FIT. The co-variables of models and the various thresholds of IgG or total proteins used to define FIT were included in the dataset and in the meta-regressions. The economic model was secondly run, considering costs of extra diseases and mortality in case of FIT. All input parameters were laws of distribution and not point estimates. The model was run using Scilab with 10,000 iterations, and 95% prediction intervals (PIs) were calculated.

To define the resources to be allocated for FIT control, the net value at the farm level was calculated and the optimal economic situation was defined as the maximal net value. Technical indicators corresponding to the economic optimum can then be defined. The net value included (i) the production linked to calves, (ii) the cost of FIT for the given herd and for FIT prevalence and (iii) the cost of FIT prevention, which was estimated through time allocated to colostrum feeding. The relationship between time spent to feed colostrum and the prevalence of FIT was established thanks to literature. Cost of labor was established according to various scenarios so as to fit the field situations.

Results: The metaanalysis standardized the OR for mortality and morbidity by a unique threshold of total proteins (<50 g/L) or IgG (<10 g/L) to define FIT. The OR [and 95% confidence interval] of mortality, respiratory diseases and diarrhea were 2.12 [1.4-3.1], 1.75 [1.5-2.0] and 1.51 [1.05-2.17] for calves with FIT compared to no FIT, respectively. Calves with FIT has a 53 g. lower average daily gain compared to calves without FIT. These 4 components were included in the total cost of FIT.

The total cost [and 95 % PIs] of FIT was 60 euros [10-140] and 80 euros [20-110] per calf with FIT, for dairy and beef calves, respectively. Mortality, respiratory diseases, diarrhea and average daily gain contributed for 26, 16, 13 and 45 % of the total cost. The total cost of one case can be easily used in the field to calculate the avoidable costs of FIT for a given farm, thanks to comparison of the initial prevalence and the expected prevalence after changes in practices, multiplied by the unit total cost.

The optimal time to feed colostrum was around 15 min per calf, whatever the total cost of labor. Resources to be allocated for FIT management did not show important changes between scenarios. Importantly, increasing this duration led to small decreased in the farm net value, but decreasing this duration led to hugh decrease in the farm net value. Only very high cost of labor led to changes in the optimal time to be spent to feed colostrum. The optimal mortality and prevalence of respiratory diseases and diarrhea calculated at the economic optimum were 5, 29 and 23 % for most of the scenarios.

Conclusions: The total cost of one case of FIT is of interest to help decision making at farm level. Within few minutes, the practitioner can perform a raw estimation of the total cost. To prevent any error in decision making, both the mean cost and the ranges of the prediction interval have to be considered within the economic reasoning at farm level.

The present results also demonstrate the economic justification to spend at least 15 min per calf to make colostrum be ingested.

P04-004-013

Effects of acute clinical infection with the Schmallenberg virus on milk yield, fertility and veterinary costs in Swiss dairy herdsMireille Meylan¹, Marianne Wüthrich¹, Isabel Lechner², Marlis Aebi¹, Andrea Vöggtlin³, Horst Posthaus⁴, Getraud Schüpbach-Regula²¹Clinic for Ruminants, ²Veterinary Public Health Institute, ³Institute of Virology and Immunology, ⁴Institute for Animal Pathology, Vetsuisse Faculty, University of Berne, Berne, Switzerland

Objectives: Schmallenberg virus (SBV) was first detected in Switzerland in July 2012 and many Swiss dairy farmers reported acute clinical signs in dairy cattle during the spread of the virus until December 2012. The objectives of the present study were to investigate the effects of an acute infection with SBV on milk yield, fertility and veterinary costs in dairy farms with clinical signs of SBV infection (case farms) and to compare them to a matched control group of dairy farms in which cattle did not show clinical signs of SBV infection.

Materials and Methods: Case and control farms were visited once between May and December 2013, and a questionnaire was filled with the herd managers. Data for cost of treatment and selected fertility parameters were retrieved from the veterinary bills, and data on milk yield and fertility were extracted from reports of the breeding associations. Data from 77 case farms, 84 control farms, and 77 matched pairs were available for analysis of variables from the questionnaire. Seventy-three case farms, 78 control farms, and 70 pairs had complete data for the analysis of veterinary costs and fertility parameters obtained from the veterinary bills (dystocia requiring veterinary assistance, retained fetal membranes, intrauterine treatments). Analyses of data from the breeding associations could be performed with 70 cases, 72 controls, and 63 pairs; 53 control and 52 case farms as well as 47 pairs were included in the analysis of calving intervals. In the statistical analyses, two different comparisons were made. Case farms were compared to control farms, and the time periods before, during and after SBV infection were compared within case and control farms, respectively. Data analysis was performed with univariable analysis followed by multivariable analysis in mixed regression models.

Results: Herd size was significantly ($p < 0.001$) higher in case farms (33 cows, $n = 77$) than in control farms (25 cows, $n = 84$). Within case herds, 14.8% (median) of the cows showed acute clinical signs. Managers from case farms indicated to have observed a higher abortion rate during the year with SBV (6.5%) than in the previous year (3.7%). Other fertility parameters showed no significant differences between the two groups. The general veterinary costs per cow from July to December 2012 were significantly higher ($p = 0.02$) in case (CHF 19.80; EUR 16.50) than in control farms (CHF 15.90; EUR 13.25). No differences in milk yield were found between groups, but there was a significant decrease in milk production in case farms in the second half year in 2012 compared to the

same period in 2011 ($p < 0.001$) and 2013 ($p = 0.009$). The average daily milk yield per cow (both groups together) was +0.73 kg higher ($p = 0.03$) in the second half year 2011 and +0.52 kg ($p = 0.12$) in the second half year 2013 compared to the same half year 2012. Fifty-seven percent of the cows with acute clinical signs ($n = 461$) were treated by a veterinarian.

The average calculated loss after SBV infection for a standardized farm was CHF 1606 (EUR 1338), which can be considered as low at the national level, but the losses were subject to great fluctuations between farms, so that individual farms could have very high losses ($> CHF 10'000$, EUR 8333).

Conclusions: In general, acute SBV infection in dairy cows had a short effect on animal health, but several farmers reported a long-lasting reduction in milk production in clinically affected animals. Overall within-herd prevalence of animals showing acute clinical disease was rather low, but multiple farmers observed high rates of clinically affected cows within their herds, which could lead to important economic losses in individual affected farms. Nonetheless, the economic impact of SBV infection appeared to be moderate at the national level.

Animal Health Economics

P04-004-014

Economic analysis of reproductive ultrasound examinations in a large-scale dairy herd – a field study

István Fodor¹; Zsolt Cziger²; László Ózsvári¹

¹Department of State Veterinary Medicine and Agricultural Economics, Faculty of Veterinary Science, Szent Istvan University, Budapest,

²private veterinarian, Dunaföldvár, Hungary

Objectives: The reproductive performance of the Hungarian Holstein-Friesian cow population is relatively poor compared to other ICAR member countries. Transrectal ultrasound is a valuable tool in the reproductive management of dairy cows, however, it is still not used in a large proportion of the Hungarian dairies. Therefore, the aim of our study was to quantify the impact of the reproductive ultrasound examinations on the production parameters and the profitability compared to palpation per rectum in a large-scale dairy herd.

Materials and Methods: A field trial was carried out in a 420-cow Hungarian dairy herd between 6 October 2014 and 19 February 2015. The average 305-day milk yield was 8,009 kg in 2014. After checking the uterine involution on Day 42 postpartum, healthy cows were randomly assigned into two groups. In the palpation group ($n = 30$), all reproductive examinations – including the pregnancy diagnosis 40-47 days after insemination – were performed by rectal palpation, exclusively. In the ultrasound group ($n = 32$), all reproductive checks – and the pregnancy check 30-37 days after insemination – were performed via transrectal ultrasound examination. Reproductive examinations were carried out twice per week including pregnancy checks once a week.

In the economic analysis of the application of ultrasound examinations the cost of semen, the reproductive treatment costs (weighted average cost by active ingredients) and the veterinary fee were taken into account as costs, and the reduction of losses due to days open was considered as benefit. The average cost of an open day was quantified as the margin in net milk receipts (income over feed cost) and net income from calf sales between cows with the optimal and the actual calving interval. The average costs and prices of the study period were used in the calculations, where 1 EUR = 300 HUF (milk price: 36.67 EUR cent/kg, cost of ultrasound examination: 1 EUR/examination, semen cost:

11.67 EUR/straw, cloprostenol: 90.66 EUR cent/treatment, GnRH: 1.00 EUR/treatment, GnRH [cyst]: 2.00 EUR/treatment, cefapirin: 5.67 EUR/treatment, ceftiofur: 16.66 EUR/treatment).

Results: In the ultrasound group, the proportion of pregnant cows was 5.5% higher (68.8% vs. 63.3%), and these cows received less reproductive treatments (2.9 vs. 3.9 per cow) compared to the palpation group during the experiment. Concerning the pregnant cows in the ultrasound group, days to first service and days open were reduced by 7 and 12 days (74 vs. 81 days and 106 vs. 118 days), respectively, breeding interval was 29.6 days shorter (32.0 vs. 61.6 days), and these cows required 0.4 more inseminations (2.0 vs. 1.6 per cow) to conceive compared to the pregnant cows in the palpation group. Concerning the cows remaining open in the ultrasound group, days to first service was reduced by one day (71 vs. 72 days), and these cows received 0.6 more reproductive treatments (5.6 vs. 5.0 per cow) and slightly more inseminations (2.2 vs. 2.1 per cow).

The cost of an open day accounted for 6.5 EUR on average. The average cost of a reproductive treatment was 1.24 EUR in the palpation group and 1.40 EUR in the ultrasound group. Ultrasound examinations resulted in 73.1 EUR profit (benefit - cost) per pregnant cow compared to rectal palpation. Taking all the cows into consideration, ultrasound examinations caused 4.16 EUR extra cost per cow, however, the income increased by 53.62 EUR per cow on average. Therefore, earlier conception achieved by ultrasound reproductive examinations generated 49.46 EUR profit per cow compared to the palpation per rectum method, which means about 20,000 EUR annual extra profit in this herd.

Conclusions: Reproductive ultrasound examinations enable earlier reproductive treatments and inseminations, thereby reducing days to first insemination, days open and breeding interval, and resulting in more pregnant cows within the same time frame. Despite the additional costs, ultrasound examinations yielded a remarkable amount of profit compared to palpation per rectum in this herd. Hence, herd managers should consider applying reproductive ultrasound examinations in order to improve herd reproductive performance and profitability.

A Comparison Of The Costs Of Bluetongue Virus Serotype 8 (Btv-8) Surveillance And Intervention Programmes In Austria And Switzerland Between 2005-2013

Clair L. Firth¹; Karin Lebl²; Angelika Loitsch³; Simon Stockreiter⁴; Heinzpeter Schwermer⁵; Beate Pinior¹

¹Institute of Veterinary Public Health, University of Veterinary Medicine Vienna, ²Güpfertlingstraße 33, Vienna, ³Institute for Veterinary Disease Control, Austrian Agency for Health and Food Safety (AGES), Moedling, ⁴Federal Ministry of Health, Vienna, Austria, ⁵Federal Food Safety and Veterinary Office, Bern, Switzerland

Objectives: The aim of this study was to assess the temporal and spatial distribution of costs incurred during the surveillance and intervention programmes to control BTV-8 in two comparable Alpine countries. Of particular interest was the proportion of costs covered by “in-kind contributions” made by the veterinary authorities and those which were reimbursed by the European Union. Finally, an assessment was made as to whether these costs are predictable and whether such predictions can be made accurately.

Materials and Methods: The total costs of the surveillance and intervention programmes in both countries were compared, with respect to “pre-outbreak”, “outbreak” and “post-outbreak” periods. The first case of BTV-8 in Switzerland was reported in 2007; in Austria in 2008. Costs were also calculated with respect to livestock units (LU). In Austria, 1 LU is defined as 500kg liveweight: approximately 1 adult cow or 6.7 adult sheep/goats. For the prediction of costs, a linear regression model was used. This model enabled the effect of animal species (cattle, sheep, goats) and the average farm size on total costs per political district to be calculated.

Results: Between 2005 and 2013, the total costs for the surveillance and intervention programmes in Austria amounted to €22.8 million, compared to €16.6 million in Switzerland. In Austria, 32% of these costs were incurred through surveillance and 68% was spent on intervention; whereas in Switzerland 94% of all costs were spent on the vaccination programme. Total vaccination costs were equivalent in both countries with around €15.5 million spent: in Austria these costs were primarily due to personnel expenditure, whereas the Swiss authorities spent almost equal proportions on personnel and material costs. The costs determined in this study for Austria were equivalent to €4.50/LU spent on surveillance and €9.64/LU spent on vaccination.

Of the total programme costs, “in-kind contributions” (e.g. blood samples taken by vets as part of their daily work) were estimated to amount to €2.1 million in Austria and just €229,681 in Switzerland. However, in-kind contributions are notoriously difficult to define and for this reason these costs are likely to have been up to 10-fold higher. The European Union reimbursed the Austrian state €4.9 million for costs incurred in enacting EU regulation 1266/2007.

The linear regression model demonstrated a good level of predictability for intervention costs in both countries: $R^2=0.97$ in Austria; $R^2=0.98$ in Switzerland. Given the large number of diagnostic tests available and differences in veterinary costs according to farm altitude etc., the model for predicting surveillance costs was found to be less accurate ($R^2=0.45$ in Austria; $R^2=0.28$ in Switzerland).

Conclusions: Despite Austria and Switzerland being comparable in terms of ruminant stocking density, landscape and climate, this study demonstrated that substantial differences existed with respect to costs incurred by BTV-8 surveillance and intervention programmes. It is perhaps also important to note that, between 2005-2013, a total of 76 farms were infected with BTV-8 in Switzerland, and 14 farms were infected in Austria over the same period. Our study demonstrates that variations in planning, implementation, personnel, material and overall strategy lead to large variations in costs between control programmes in neighbouring countries.

Animal Health Economics

P04-004-016

Internal economic losses due to culled and diseased dairy cows

Albert Sundrum¹; Susanne Hoischen-Taubner¹; Werner Feucker²

¹Animal Nutrition and Animal Health, University of Kassel, 37213 Witzenhausen, ²Data Service Paretz GmbH, 14669 Ketzin, Germany

Objectives: Dairy cows differ considerably in their ability to adapt to their living conditions and to avoid the development of diseases and the risk of being culled. The operational management has direct impact on the portion of diseased and culled animals in the herd. Besides general

knowledge about economic impacts of production diseases, it is of high importance for the farmer to consider the degree of economic losses in the farm specific context, particularly the losses that occur in the case of diseased or culled cows in comparison to those animals that keep healthy. The objective of the study was to provide this information to the farm management.

Materials and Methods: The missing link between key economic figures and production data is seen as a significant weak point when trying to assess cost-benefit ratios in the context of production diseases. A new approach has been developed that enables an economic assessment of the consequences of increased rates of morbidity and culling as well as productivity losses, based on the production data of individual animals deriving from monthly available milk recordings. Data analysis is relying on a newly developed tool relying on the herd management software Herde® and based on individual lactation curves within a defined period of 365 days. Data transformation of culled cows and those that are persistent in the 365-day dimension is conducted separately for each lactation number. The average lactation curve progressions are linked with indicators of fertility (such as period between calving and first service, days open, pregnancy, etc.) and with the farm specific economic figures of production costs and revenues, reported in the agricultural production branch ‘cattle’ (BZA-cattle), including the realized milk revenue and sales of breeding animals and costs for replacement by heifers. The keeping costs include all costs that an average stock cow causes each day, based on the full-cost accounting. Also the revenue of slaughtered cows is included in the calculations. To assess the meaningfulness of the results deriving from this approach, 30 commercial dairy farms in Germany were selected in relation to general characteristics, resources, and management procedures.

Results: Data calculations revealed a large variation in productivity and economic losses between and within dairy herds. The variation resulted in considerable differences in the economic impacts of culled cows in relation to persistent cows regarding economic losses, and in the return of investment. The approach enables an action-related allocation of figures to assess the efficiency of production processes and the contribution of defined animal groups (e.g. healthy, diseased or culled cows) to the operating results. Moreover, robust assessments of the potential impact of changes concerning the economy can be made through an in-house comparison between defined groups of animals. Assessments of the accuracy of parameters provided good results, however, depending, on herd size. The profitability-analysis enables to quantify the impacts of variable factors (e.g. milk price, feed costs, culling rates, calving interval, prevalence of production diseases) and their changes over time on the development of livestock with its achievements and its economy. It facilitates the estimation of the contribution of different sub-groups to profit and losses, respectively, in relation to the overall economic results of the dairy production, providing decisive criteria for evaluating the effectiveness of operation.

Conclusions: Cost-benefit calculations are crucial to identify the most efficient measures and to show where investigations in animal health management may result in monetary benefits that exceed the investment. The new farm centric approach provides insights into the cost structure of a farm that have not been accessible before, thereby creating awareness and economic incentives for an improved animal health management.

P04-004-017

Socioeconomic Impacts Of Foot-And-Mouth Disease On Smallholder Farmers In South-East Asia

Peter Windsor¹, Sonevilay Nampanya¹, Syseng Khounsouy², Jim Young¹, Russell Bush¹ and Mekong Livestock Research Group

¹Faculty of Veterinary Science, University of Sydney, Camden, Australia, ²Department of Livestock and Fisheries, Luang Prabang, Lao People's Democratic Republic

Objectives: In the global PCP (Progressive Control Pathway) for FMD, Pool I containing Southeastern and East Asia, is the second most advanced region involved in FMD control, with eradication achieved from Indonesia in 1984 and the Philippines in 2011, and a current OIE Roadmap encouraging regional FMD control through the SEACFMD program. To guide allocation of investments in FMD control, we conducted research on the socioeconomic impacts of FMD on large ruminant smallholders in Laos in 2011-12, including studies of gender, household financial status and farmer husbandry practices, including options and costs for treatment of FMD-affected animals.

Materials and Methods: Household level impacts of FMD were assessed by separate surveys (n=124, n=310) enabling stratification of wealth status as 'poor, medium or well-off' and FMD-attributable losses included those from mortality, morbidity and costs of treatments. National level FMD impacts were determined from reports of 2011-2013 FMD outbreaks and estimates based on: (i) total FMD financial losses at the village level; and (ii) the costs of FMD responses and other related costs but excluding the costs of revenue forgone. A Monte Carlo simulation accounted for scenarios of over- and under-reporting of FMD and above data used to estimate the benefit to cost ratio of the current vaccination program.

Results: Losses were USD436 (±92) in 'poor' and USD949 (±76) in 'well off' household categories (P < 0.001), being 128% and 49% of income from the sale of large ruminants, respectively. Variation in financial losses reflected differences in morbidity, farmer husbandry practices and importantly, choice of treatments, with adverse financial impacts where antibiotics were used. Monte Carlo simulation estimated that national financial losses in 2011 may have exceeded USD 102m, almost 12% of the estimated farm gate value of the national herd. Partial budget analysis of biannual FMD vaccination indicated an average net benefit of USD 22 and USD 33 for cattle and buffalo, respectively. Benefit to cost ratio of the current FMD vaccination program in northern Laos was estimated at 5.3.

Conclusions: FMD caused substantial financial impacts on households, villages and the national economy of Laos, with most severe impacts on poorer households, particularly as the inappropriate use of antibiotics for FMD created a financial burden. Females had a significant role in large ruminant production and financial management and extension programs that promote household investments in FMD control are financially justifiable and should involve women and importantly, avoid the use of antibiotics.

Comments: These findings support continuation of investments by international donors in FMD control in this region, including vaccination and biosecurity education. Socioeconomic perspectives are important where resources are severely limited and household and national expenditure on a relatively low mortality livestock disease that is of enormous global significance can be difficult to justify in developing countries, particularly when inappropriate animal treatment options are applied and unfortunately advocated by authorities.

P04-004-018

Decision Support Tool For Implementing Vaccination Against Mastitis

Jehan Ettema¹, Michal Pochodyla², Henrik Schmidt³

¹SimHerd A/S, Tjele, Denmark, ²Laboratorios HIPRA, Amer (Girona), Spain, ³HIPRA Denmark, Kolding, Denmark

Objectives: Recent studies have documented the efficacy of STARTVAC against *S. aureus* (Schukken et al. 2014) and *E. coli* (Bradley et al. 2014). The former study stressed that the economic impact of STARTVAC in a specific herd depends on the herd's infection level with *S. aureus* and management level for udder health, such as milking procedures and culling regime of infected cows. Bradley et al. (2014) reported a return on investment of 2.6:1, but in the article it is stressed that this concerns the effects on milk yield alone and not the effect of the vaccine on the reduced severity of clinical cases.

Materials and Methods: SimHerd is a stochastic, mechanistic and dynamic simulation model of a dairy herd including young stock (Østergaard et al. 2005). The web-based model is routinely used by Danish veterinary practitioners and farm advisors and it quantifies the economic benefits of improving e.g. reproductive performance. In a collaboration between SimHerd Inc. and HIPRA, a decision support module was added to the existing SimHerd model that can estimate the economic return of using STARTVAC in a specific herd. The empirical evidence of the aforementioned studies was incorporated in the SimHerd model. Furthermore, SimHerd simulated the efficacy of the vaccine against *S. aureus* using the herd's infection level of *S. aureus* as herd specific data, but also for four different management levels for udder health. The economic impact of the vaccine against *E. coli* was estimated by simulating a scenario in which the vaccine's effect on milk yield alone was simulated and a scenario in which the effect on milk yield and reduced severity of mastitis cases was simulated. The herd's level of mastitis incidence and distribution of severities was entered into the model as herd specific data. Other herd specific data that was used in the SimHerd model, was among others milk yield level, reproductive performance, replacement rate and other diseases treatments.

Results: The simulated results of the four *S. aureus* scenarios and two *E. coli* scenarios are summarized in a three-page report in pdf. The report contains bar diagrams showing changes in net return per cow per year for the different scenarios, in contrast to the costs of the vaccine, represented by a horizontal line in the bar chart. The report furthermore presents development of economic return over time and technical details for each scenario, such as changes in milk yield per cow per year and culling rate. The simulated increase in net return (excluding costs of vaccination) when using STARTVAC in a typical 200-cow Danish dairy herd is €3087 and €13825 per year for the efficacy against *S. aureus*, in case the management level is poor and good, respectively. The increase in net return with respect to the efficacy against *E. coli* is €7919 and €14630 when simulating the effects of milk yield alone and the effects of both milk yield and reduced severity of clinical cases, respectively.

Conclusions: SimHerd with the additional module for estimating the economic impact of STARTVAC has since the development been used by Danish veterinarians. The simulated results of the vaccine efficacy are used for decision support but also in the valuable discussion between farmer and veterinarian on management practices of udder health. Simherd has already supported decisions to vaccinate herds in Denmark.

Evaluating Periparturient Disease Costs in Dairy Cows Using the Economic Assessment Tool

Michael Overton^{1,*}¹Elanco Knowledge Solutions, Elanco Animal Health, Greenfield, United States

Objectives: The Vital 90™ Days span from 60 d prior to calving through 30 d in lactation. During this time, dairy cows experience negative energy balance and immune suppression as well as metabolic and infectious problems. Cows that experience these issues often have higher culling and mortality risks; survivors often experience diminished milk production and reproduction. The objective of this project was to examine the total cost associated with transition dairy cows, including investment and consequence costs, via use of the Economic Assessment Tool and to understand factors that impact these costs.

Materials and Methods: The Economic Assessment Tool was created to understand the total costs incurred by dairy cows from dry off through the first 30 days of the subsequent lactation. After selection of the specific preventive procedures used in each time period by parity group (heifers vs. cows), general herd parameters such as milk price, feed price, culling risk, number of cows calving (by parity), fresh cow value, and market price for cull cows are entered. Fresh cow disease incidence is entered by parity group and the user specifies the typical treatment approach used for each disease including dose, duration, and milk withdrawal times. The model calculates the direct costs (diagnostics, therapeutics, discarded milk, labor, and death losses) and indirect costs (future milk losses, culling losses, and the cost of other attributable diseases). By summing the total direct and indirect disease costs, the total consequence cost is determined. Finally, the tool adds the total investment cost to the total consequence cost and reports The Vital 90 Days cost per cow calving by parity. Multivariate regression using the Fit Model platform and Standard Least Squares within JMP 12.1.0 software was used to examine the general management factors associated with herd-level disease consequence cost and as well as cow-level disease costs including ketosis and mastitis.

Results: The mean total Cost per Cow Calving observed in 133 North American herds was \$263 (std dev of \$81), with \$116 due to investment costs and \$147 due to disease consequence costs. Mean ketosis and mastitis costs/case across herds (\$102 and \$387, respectively) were very similar to recently published results. Significant factors associated with disease cost included average cow value, how waste milk is utilized, milk price, labor cost, market cow value, culling risk, and feed cost. The relative importance of each variable varied with the disease under consideration.

Conclusions: Considerable financial and management resources are devoted to mitigating the impacts of metabolic and infectious challenges that occur during The Vital 90 Days, but few have quantified the cost incurred by each cow. Indirect disease costs tended to be larger than direct disease costs and total consequence cost of disease was greater than the investment cost for the average dairy. Considerable variation exists across herds but use of the Economic Assessment Tool to generate the Vital 90™ Days cost per calving should help producers make better decisions and improve their understanding of how disease management impacts profitability.

Mastitis associated economic loss in Canadian dairy farms

Mahjoob Aghamohammadi^{1,2}; David F. Kelton^{2,3}; Herman W. Barkema²; Henk Hogeveen⁵; Greg P. Keefe²; Kehar Singh⁶; Simon Dufour^{1,2}

¹Faculté de médecine vétérinaire, Université de Montréal, ²Canadian Bovine Mastitis and Milk Quality Research Network, St-Hyacinthe, ³Ontario Veterinary College, University of Guelph, Guelph, ⁴Faculty of Veterinary Medicine, University of Calgary, Calgary, Canada, ⁵Wageningen University and Research Center, Wageningen, Netherlands, ⁶Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Canada

Objectives: Mastitis imposes significant economic losses on the Canadian dairy industry. Estimating the overall economic burden induced by this disease in a country is a crucial step to rationalize control measures to cover priorities. The main objective of the current study is to estimate the total cost of mastitis in Canada in 2014 and the reduction in losses that could be gained under various putative udder health improvement scenarios.

Materials and Methods: An economic calculation model was developed for computing the farm level costs using cow-level data. All remarkable components of economic losses due to mastitis were listed according to a review by Halasa et al. (2007). These components included milk losses, discarded milk, drugs, veterinary visits, diagnosis, product quality, labor, culling, death, material and investments. Costs related to practices used strictly for mastitis prevention (e.g. dry cow therapy, teat disinfection) were taken into account in this later component. For each component, equations required to calculate the losses due to that component were prepared. The model was designed so it can be adapted for systems with and without supply management (milk quota). To feed the model, Dairy Herd Improvement (DHI) and clinical mastitis (CM) data can be used as well as data on various dairy production inputs and outputs.

Results: This model will be applied to all dairy producers in the 10 Canadian provinces to compute costs at the provincial and national levels. In the current study, required data will be obtained using historical DHI data from the 9,600 Canadian dairies currently enrolled in milk recording programs. DHI data will be simulated for the 2,400 non-DHI dairies by drawing a number of herds with replacement within the DHI herds. The CM distribution from the National cohort of Dairy Farms of the Canadian Bovine Mastitis and Milk Quality Research Network will be used in the model (Reyher et al. 2011). A sensitivity analysis will be used to evaluate the impact of a potential reduction in CM incidence on the total cost, since no recent studies have been conducted on this topic in Canada. Some values will be obtained from a questionnaire which will be administered to 374 Canadian dairy producers participating in an ongoing study, the Canadian National Dairy Study 2015. In addition, estimated cost of production reported in an annual study conducted by the Canadian Dairy Commission will be used. Costs will be reported per year at the provincial and national levels as total mastitis costs, costs due to subclinical mastitis and CM independently, average mastitis costs per milking cow, average costs of subclinical mastitis per milking cow, average CM cost per milking cow, and average CM cost per affected cow.

Conclusions: This study will be the first to provide an estimate of mastitis costs in Canada and to report the attributed component costs. Furthermore, the developed economic model can be used to assess changes over time at the national level and can be adapted for use in different countries with or without a supply management system.

Acknowledgment: This project was supported by a contribution from the Dairy Research Cluster Initiative (Dairy Farmers of Canada, Agriculture and Agri-Food Canada, the Canadian Dairy Network and the Canadian Dairy Commission).

Annual cost of sanitation of farms with bovine brucellosis in Uruguay

Jose Piaggio¹, Bruno Lanfranco², Marcelo Rodriguez³, Federico Fernandez³, Alfredo Garin³, Andres Gil¹

¹Bioestadística, Facultad de Veterinaria - Uruguay, ²INIA, ³DGSG, MGAP, Montevideo, Uruguay

Objectives: In Uruguay, the program of Bovine Brucellosis (BBr) is based on the principle of testing and slaughtering. Individual prevalence is estimated at 0.2%, reaching 0.8% at farm level. Currently, there are 344 farms under quarantine in the country. An "insurance system" compensates farmers for the price differential received from the slaughterhouse, for the sacrifice of positive animals.

The objective was estimating the annual cost of the sanitary measures applied to clean BBr hotbeds in Uruguay.

Materials and Methods: A stochastic simulation model was built, stratifying by farm type and herd size. The inputs were: number of new foci, number of precedent foci, herd size, per-head costs of bleeding and serologic diagnosis, cost of vaccine, and the amounts covered by the insurance for both dairy and beef cattle. Information System for Animal Health data were used to define the distributions of foci per stratum and initial prevalence at detection. The number of farms per stratum and herd population used to define the probability distributions was obtained from DICOSE. It was assumed serology every 120 days. The output of the model included total annual country-level costs of the sanitary program, including bleeding, diagnosis, and vaccination, and total compensation paid to farmers for the slaughter of positive animals in all existing foci.

Results: Serology costs averaged US\$ 725,000, corresponding to 137,460 serology, of 68730 cattle.

Vaccine application averaged US\$ 350,000, corresponding to 123338 cattle vaccinated.

Compensation for the slaughter of cattle reactors have averaged US \$ 1,290,000 that came from a number of cattle compensated 6953, 96% of which correspond to beef and dairy cattle 4%.

The estimated average annual total cost for serology, vaccination and compensation for slaughtered cattle reactors amounting US\$ 2,360,000. Ninety-five percent of the iterations performed by the model ranged from US\$ 1,558,000 to US\$ 3,504,000.

Conclusions: Considering the estimates of sanitation costs along with the annual costs of the insurance allowed the inclusion of new actions

to be covered by the latter, as the cost of foci sanitation, the serology tracing and vaccination of neighboring farms.

Comments: Once detected the infection in a herd, any movement of susceptible animals other than for slaughter is forbidden. All sites epidemiologically related to the interdicted herd are traced and investigated. All females are vaccinated. A periodical serology with elimination of reactors is performed until two subsequent negative rounds are obtained, with a minimum interval of four months.

A simple method to calculate the cost of mastitis under Spanish field conditions

Joaquim Baucells^{1,2}

¹Centre Veterinari de Tona, Tona, ²Universidad Autonoma de Barcelona, Barcelona, Spain

Objectives: The calculation of the cost of mastitis is complex and has been associated with multiple factors: the disease (prevalence, severity, effects, aetiology, concurrent disorders, etc.), the animal (lactation status, age, productive level), the setting (treatment protocols, methods of prevention, elimination, management), and prices (value of different expenses, price of milk, penalties and premiums). The complexity and heterogeneity of the many variables involved and their interactions promote duplication of effects and errors, and affect the credibility of results.

Materials and Methods: When trying to calculate the cost of mastitis at field level, simplicity and clarity are important, so we calculate the economic cost on the basis of 3 factors:

- 1.- Expense associated with treatment:
It takes into account the appearance of new cases of clinical mastitis (CM), the price of milk and the productive level of the farm, and the days that milk is discarded (it is assumed for 8 days, and none is used to feed calves).
- 2.- Losses in quality premium incentives
Part of the European dairy industry penalises or rewards the milk price on the basis of somatic cell counts (SCC). Therefore, the price of milk is strongly affected by the incidence of mastitis.
- 3.- Production losses due to high SCC.
There is a strong correlation between inflammatory processes like mastitis and the reduction in the functionality of the glandular parenchyma of the udder. The linear score (LS) is a method of interpreting SCC that is strongly associated to milk production

Results: In the following table this methodology is applied to a farm with 100 milking cows and 11,200 L/cow/year.

Table 1: Cost per clinical case

A	Average medicine costs (€)	20 €/case
B	Number of days for discarded milk (days)	8 days
C	Average production (L/cow/day)	35 L
D	Average milk price (€/L)	0.358 €.
E	Cost of professional fees (€)	20 €/case
F	Monthly percentage of new cases (%)	2 %
G	Number of cows per farm (No)	100

H	BxCxD Discarded milk, value(€)	100.24 €
I	A+E+H Total losses per case(€)	140.24 €
J	GxFxH Cost per farm/month(€)	280.48 €
K	Jx12 Cost per farm per year (€)	3,365.76 €
L	K/G Impact per cow (€/cow/year)	33.7 €

Table 2: quality premium incentives

A	Basis for SCC premium (x 100 cells/ml)	< 200
B	Bonus quality premium(€/MT)	6 €
C	Basis for SCC penalty (x 100 cells/ml)	> 300
D	Penalization (€/Tm)	-6 €
E	Monthly production supplied to industry (MT)	94
F	Number of animals	100
G	D-B Class A differential (€/MT)	-12 €
H	G*E Monthly loss (€/month)	-1,128 €/month
I	H x 12 Annual loss (€/year)	-13,536 €
J	I/F Impact per cow €/cow/year)	135 €

Table 3: Milk losses due to a high SCC

A	Total cows (No.)	100
B	Annual production (t)	1,120
C	Mean annual SCC (cells/ml)	320
D	LS	5
E	Milk price (€/L)	0.358
F	Average feed cost (€/L)	0.200
G	Annual estimated losses according to LS (L/cow/year)	540
H	G x A Total milk loss (L)	54,000
I	E-F Economic cost of milk not produced (€/L)	0.158
J	H x I Estimated annual loss (€/year)	-8,532 €
K	J/A Impact per cow (€/cow/year)	85.32 €

Conclusions: There is widespread agreement between specialists and researchers that for the majority of modern, advanced dairy farms, bovine mastitis is one of the major causes of economic losses due to disease and that therefore, quantification of these losses is an interesting and useful task. The exercise presented in this paper is a useful tool for the calculation of costs in field conditions in a simple and clear way.

Animal Health Economics

P04-004-023

Estimating the Impact of Mastitis and Metritis in Commercial Dairy Herds

 Michael Overton^{1,*}
¹Elanco Knowledge Solutions, Elanco Animal Health, Greenfield, United States

Objectives: The Vital 90™ Days span the 60 days prior to calving through 30 days in lactation. During this time, dairy cows experience negative energy balance and immune suppression as well as metabolic and infectious problems that often lead to clinical disease with increased

culling and mortality risks, diminished milk production and impaired reproduction. The objective of this project was to evaluate the impact of metritis and mastitis, occurring within the first 30 days of lactation, on production, reproduction and culling across the lactation and to evaluate the impact of disease misclassification on-farm on the resulting estimated disease impact.

Materials and Methods: On-farm dairy records covering a 12-month period of calving were collected from Elanco's Dairy Data Access System™, screened for consistency of recording and filtered to include only Holsteins. Animals were followed for 300 days after calving or until culled or calving again. Descriptive statistics were used to describe parity, twinning, age at first calving, average p305ME milk, and disease incidence. Multivariate nominal logistic regression was used to examine relationships between management or cow-level variables and risk of metritis and mastitis. Multivariate regression using the Fit Model platform and Standard Least Squares within JMP 12.1.0 software was used to evaluate the impact of metritis and mastitis on milk production while adjusting for covariates. Univariate survival plots for time to herd removal or time to pregnancy were plotted for each disease. Cox proportional hazards models were created to evaluate time to removal or time to pregnancy while accounting for important covariates. Risk ratios to compare the risk of culling or pregnancy were computed from the parameter estimates. Two individual herds that aggressively detect, record and treat postpartum disease were evaluated apart from the large data set as previously described to investigate the impact of disease misclassification. Within the smaller data set, cows recorded as having mild disease were relabeled as "normal" to mimic common behavior on commercial farms where only the most severe disease is recorded. The data were analyzed yet again to compare the estimated impacts.

Results: The final data set included more than 50,000 cow records. Cows that experienced mastitis within the first 30 days of lactation were predicted to lose ~2500 lbs of p305ME milk, had ~1.2 times higher odds of being culled by 300 days and had lower odds of becoming pregnant. Cows with metritis were predicted to lose 600 to 1000 lbs of p305ME milk and had similar odds of premature culling as with mastitis. However, cows with metritis had ~30% lower odds of conceiving by 300 d. Misclassifying cows that had mild disease into the normal category significantly underestimated the negative impact of metritis and mastitis on milk production, culling and reproductive performance.

Conclusions: Metritis and mastitis occurring in the first 30 days of lactation were associated with decreased milk production, increased culling and decreased reproductive performance. While the results found in this large scale observational study are similar to published research findings, biases introduced by failing to consistently and accurately identify and record disease such as metritis and mastitis are demonstrated to underestimate the true impact of postpartum disease.

Economic Analysis On Genetic Breeding Of Three Groups Dual Purpose Heifers Humid Subtropical Climate

 Enrique Durán Meléndez^{1,*} Rene Carlos Calderón Robles²
¹Universidad Autónoma Benito Juárez de Oaxaca, Oaxaca, ²Instituto Nacional de Investigaciones Agrícolas y Pecuarias, Hueytamalco, Puebla, Mexico

Objectives: This study was a collaborative research work between

the Autonomous University Benito Juarez of Oaxaca and the National Institute of Agricultural and Livestock Research whose goal was to estimate the cost of production of the three genetic groups of heifers dual purpose (meat and milk) from the birth to the first child to determine what is the most economical in terms of production costs.

Materials and Methods: The methodology used was that proposed by Aguilar et al. 2001. The economic data was analyzed from 2008 to 2010 at the Department of Livestock Production dual purpose (DP) "Las Margaritas" in Hueytamalco, Pue with an altitude of 500 msnm, it has a humid subtropical climate with average annual temperature 21°C and 90% average humidity. 202 cattle were handled on average each month in an area of 98 hectares. Also it was necessary to consult the records of income and expenditure of the resources generated and used in the production unit, also the books that record the inputs and outputs of all products warehouse and sales invoices and payments services. Variable costs (VC), fixed costs (CF) and total costs (CT) were determined from birth to birth, in this stage were included separately stages from birth to weaning and weaning to first birth.

Results: The results were \$ 1674.43 and \$ 715.57 for CV and CF respectively, covering the period from birth to weaning and was the same for all three genotypes. Weaning at first birth CVs were \$ 7,141.41 for genotype Holstein / Zebu (Hol / Ce), \$ 7554.68 for Brown Swiss x Cebu (SP / Ce) and \$ 6669.30 for the Simmental x Cebu (Sim / Ce) and CF \$ 485.69 for Hol / Ce, \$ 513.59 for SP / Ce and \$ 455.89 for Sim / Ce. From birth to the first delivery were \$ 10,019.10, \$ 10,460.21 and \$ 9,547.19 for Hol / Ce, SP / Ce and Sim / Ce, respectively. In economic terms, it was less expensive to produce replacement heifers Sim / Ce in the DP systems from weaning to the first delivery.

Conclusions: It can be concluded that the dual purpose was more economical to produce heifers at first calving genotype Sim / Ce, followed by Hol / Ce and finally the SP / Ce, which implies an obvious savings in production costs, however this does not suggest that the most profitable since the latter probably compensate with subsequent lactations investment used during development.

The Economic Impact Of Decreased Milk Production Due To Subclinical Mastitis In East German Dairy Herds

Martin Pfützner^{1,2}; László Ózsvári¹

¹Department of State Veterinary Medicine and Agricultural Economics, Szent Istvan University Faculty of Veterinary Science, Budapest, Hungary, ²Tierärztliche Praxis am Weinberg, Jessen (Elster), Germany

Objectives: Nowadays mastitis has been identified as the most costly disease within the dairy industry. Economics of clinical mastitis have been subject to many recent studies. However, the subclinical form of mastitis has often been suspected to have a large influence on the revenue of a farm, but has been analysed rarely. According to very recent publications, 50,000 somatic cells/ml milk is used as a cut off value indicating inflammatory changes in the udder. The aim of this study was, to provide adequate information on the revenue loss of East-German dairy farms due to subclinical mastitis.

Materials and Methods: The data was taken from 12 farms in the Elbe-Elster region in the east of Germany. The total number of dairy cows surveyed in this study was 7,648 and their average daily milk production

was 31.98 kg. The individual cow's milk composition was tested by a Fossomatic analyser once a month, two to three times on the test day, according to the number of milking, in the period of June 2011 to June 2012. The average somatic cell count (SCC) of the surveyed farms' population was 284,320 cells/ml. The 50,000 cells/ml cut off value was used to calculate the decrease in milk production due to subclinical mastitis. In Germany and other milk exporting countries worldwide 250,000 somatic cells/ml is the recognised cut off point for supreme milk price payment. The average milk production of three cow groups (50,000-100,000, SCC/ml, 100,001-250,000 SCC/ml and over 250,000 SCC/ml) were compared to that of cows with an SCC less than 50,000 cells/ml.

Results: The results of this study show that subclinical mastitis causes a large milk yield depression. Even cows with an SCC higher than 50,000 cells/ml, but below 100,000 cells/ml showed a remarkable milk production loss of over 8%, resulting in 908.9 kg less milk during the lactation which really underlines that inflammatory changes must be present in cows showing a SCC of more than 50,000 cells/ml. Cows that had an average SCC between 100,001-250,000 cells/ml showed a reduced milk production of over 15%, which equals 1,650.05 kg milk loss during the lactation, even though this is still lower than the average SCC of 284,320 cells/ml. Average figures on an individual basis showed a daily decrease in milk production of 2.98 kg, 5.41 kg and 6.41 kg for a somatic cell count of 50.001-100,000 cells/ml, 100,001-250,000 cells/ml and over 250,001 cells/ml, respectively.

Based on the average milk price in the survey period, a single cow according to the aforementioned SCC classification showed a loss of € 294.85, € 536.80 and € 634.40 per lactation, respectively, in gross milk receipts. On an average herd level which was 637 dairy cows in this study, a total decrease of gross milk receipts was estimated to be almost € 241,000.00 per year. The feed costs were seen as fixed costs, hence, the possible savings owing to the lower milk production was not taken into account. The total loss due to both clinical and subclinical mastitis was amounted to more than € 273,000.00 a year in an average herd, taking the cost of premature disposal, discarded milk and reduced milk receipts into account.

Conclusions: The findings show that the reduced milk receipts due to lower milk production of cows with an SCC higher than 50,000 cells/ml, had the largest economic consequences, even larger than the generally accepted cut off value of 100,000 cells/ml for subclinical mastitis. The subclinical forms of udder diseases are often hard to distinguish for herd managers and accordingly fall into the responsibility of the veterinarian. They also often cause a far larger economic damage than the clinical forms, which is underlined by this study, hence they need far more attention.

Animal Health Economics

P04-004-026

Sustainability indicators of the family milk production

Valentin E. Espinosa Ortiz¹; Ariadna Castillo¹; Arturo Alonso Pesado¹; Francisco Alonso Pesado¹; Luis Arturo García²; Miguel Angel Quiroz Martínez¹

¹Economy Department, Faculty of Veterinary Medicine, UNAM, ²Animal Production, Universidad Autónoma Metropolitana Xoch., Mexico, Mexico

Objectives: Economic, social and environmental factors were evaluated in eighteen family dairy systems in México highland, in order

to characterize their production systems and to know their level of sustainability.

Materials and Methods: "Frame for the evaluation of the management systems based on sustainable indicators (MESMIS in spanish)" method was used to characterize production systems and to identify, in a practical way, the strengths and weaknesses of them.

Eighteen family dairy farms were evaluated in communities of the Mexican highlands, in the state of Michoacán; where the weather is tempered (14.1 to 29.9°C) and has a rain season in summer (897.7 mm annual rainfall). The study was performed from January to May.

The benchmarks selected in order to evaluate the farms were efficiency, quality, management practices, system continuity, the ability to change, middleman, outside supplies, incomes, job generation, self consumptions, quality of life and organization. As part of this indicators, the next variables were evaluated: milk yield, production cost of 1 lt of milk, physicochemical characteristic of the soil, manure management, volume of the milk sales, marketing sales, adoption and implementation of technologies, gross marketing margin, consumption of outside supplies, type and quantity of incomes, use of wage labor, use of family workforce, self consumption of milk, public service access with type and structure and proper level of decision making capacity.

Results: The main values based on the criteria evaluated were the indicators of perception in the farmers, use of wage labor, soil characteristics and milk self consumptions, which finally leads to social stability in these communities.

It was observed that the application of some technologies allows strengthen the criteria of sustainability in the three evaluated areas (economical, social and environmental)

It was found that the production dairy systems in Maravatío, Michoacán, tend to the sustainability as long as the management of their components is performed in an integral way, with constant technological innovations, knowledge, social and practices materials.

Finally, three different marketing channels were identified in all of them, which allows them to have a gross marketing margin of 28.7%

Conclusions: In conclusion, under the methodology of MESMIS, all the factors involved in the small farms sustainable way of life can be evaluated with accuracy.

In this study, it was found that the small rural farm systems of this Mexican region has milk production as their main economic activity, which besides self consumption, allows them to have an important economic income for the survival way of life of this rural families with his own natural resources, with economical, social and environmental sustainability.

P02-002-001

Examination of the responsiveness of the leukocyte environment in beef calves to weaning stress using molecular biomarkers

Bernadette Earley¹, Aran O'Loughlin¹, Mark McGee²

¹Animal and Bioscience Research Department, AGRIC, ²Livestock Systems Research Department, AGRIC, Teagasc, Grange, Dunsany, Co. Meath, Ireland

Objectives: The molecular mechanisms by which stress induces the development of pathologies remains unclear. In cattle, a number of necessary husbandry practices have been shown to activate the stress response, yet very little is known about the impact these have at the molecular level. The objectives of the study were i), to characterise, in male and female beef calves, the immune response to weaning stress in bovine leukocytes at the physiological and molecular levels, and ii), assess the difference between calves weaned in the presence of the dam and those weaned and penned away from the dam.

Materials and Methods: Twenty-eight clinically healthy, three-quarter bred Simmental beef calves were housed indoors on slatted floor pens with their dams on day (d) -28 of the study. The calves were offered a new diet of grass silage and had free access to concentrates. At weaning (d 0), the cows were removed and the calves were regrouped, mimicking social reorganisation, and allocated to one of four treatments: (i) females weaned beside the dam (n = 7; mean weight (s.d.) 267.3 (45.1) kg; mean age (s.d.) 227 (17.9) d), (ii) females weaned away from dam (n = 7; mean weight (s.d.) 274.1 (35.3) kg; mean age (s.d.) 224 (25.1) d), (iii) males weaned beside the dam (n = 7; mean weight (s.d.) 270.6 (69.8) kg; mean age (s.d.) 197 (38.1) d), or (iv) males weaned away from dam (n = 7; mean weight (s.d.) 267.9 (82.8) kg; mean age (s.d.) 209 (37.3) d). Treatments (i) and (iii) were assigned to pens adjacent to their dam. A metal grid fence prevented suckling whereas visual and auditory contact was allowed. Treatments (ii) and (iv) were assigned to pens sufficiently distant from their dam to prevent any visual or auditory contact. On d -3, 0, 1, 2, 3, 7, and 11 relative to weaning (d 0), blood samples were collected for haematology and gene expression profiling. Real-time qPCR was performed using the Applied Biosystems 7500 FAST RT-PCR equipment v2.0.1 using 1 µL of cDNA in a 20 µL reaction. Haematological and relative gene expression data were analysed (2x2 factorial design) using the PROC MIXED procedure of SAS (9.3).

Results: There was no effect (P>0.05) of gender, location and time or their interaction on total leukocyte or monocyte number. There was a location × time interaction (P<0.01) but no effect (P>0.05) of gender for total neutrophil number. Following weaning, neutrophil number increased in all calves (P<0.001) but the increase was greater (P<0.001) in calves weaned away from the dam than those weaned beside the dam. Neutrophil number returned to baseline by d 11. Lymphocyte number decreased (P<0.05) from baseline on d 2 and remained lower throughout the study. There was a gender × location interaction (P<0.01) for lymphocyte number, whereby away males had lower (P<0.05) lymphocyte numbers than near males and the opposite (P<0.01) occurred with females. There was no effect (P>0.05) of gender, location and time or their interaction on expression of IL-4 and lymphotoxin, and no effect (P>0.05) of location on IL-1β, IL-2, IL-8, IFN-γ and TNFα. Expression of IL-1β increased over 2-fold (P<0.001) from baseline on d 1 following weaning and remained increased on d 3 and 7. There was a gender × time interaction (P<0.05) for expression of IL-2, whereby an increase (P<0.05) from baseline occurred in females on d 1 but not in males. Female calves had greater (P<0.05) expression of IL-8 versus male calves. Expression of IL-8 increased more than 2-fold (P<0.001) from baseline on d 1 and remained elevated (P<0.05) on d 3. There was

no effect (P>0.05) of gender, location and time or their interaction on expression of NFκB2, p21 and haptoglobin.

Conclusions: Concerning management at weaning, it is concluded that suckled beef calves may benefit from a weaning strategy where they are allowed contact with the dam but prevented from suckling for a number of days before total separation occurs. The data also show an effect of gender in differential gene expression in response to stress with IL-2, IFN-γ and TNFα having increased expression in female calves compared with male calves. Furthermore, this study has established that a number of robust molecular biomarkers for weaning stress exist including: IL-1β, IFN-γ, TLR4, GRα and Fas.

Comments: This study utilised a model that was designed with the objective of isolating the maternal-offspring separation and social reorganisation occurring at weaning time, in order to characterise the weaning response without the associated stress resulting from simultaneous housing and novel handling. For this study, RT-qPCR analyses together with haematological profiles were examined to compare gene expression in blood leukocytes of weaned calves over a period of 7 days.

Animal Welfare

P02-002-002

The impact of insufficient winter feed on morbidity and mortality in Irish cattle and sheep in 2013

Damien Barrett¹, Micheal Casey², Gerard Murray¹, Donal Sammin²

¹Sligo RVL, Dept of Agriculture, Food and the Marine, Sligo, ²Central Veterinary Laboratory, Dept of Agriculture, Food and the Marine, Dublin, Ireland

Objectives: Anecdotal evidence from a range of sources indicated a substantial increase in animal mortality in Ireland in the winter/spring period spanning 2012/13. This was generally ascribed to the shortage of feed and the prolonged winter feeding period consequent to poor weather conditions in the summer of 2012 and the spring of 2013. The objective of this study was to evaluate available data in an attempt to objectively quantify the impact of the fodder shortage on mortality and morbidity in the Irish cattle and sheep population.

Materials and Methods: Bovine mortality data for the period January 1st to April 30th in both 2012 and 2013 was extracted from the Department of Agriculture, Food & the Marine (DAFM) Animal Identification and Movement (AIM) system, with cattle categorised by age group. The DAFM Laboratory Information Management System (LIMS) was used to compare the numbers of ovine and bovine carcasses submitted to Regional Veterinary Laboratories (RVLs) for post mortem during the study periods in both years to study mortality. Changes in morbidity were estimated using submissions of calf faecal samples to RVLs to screen for pathogens causing diarrhoea and serum samples submitted to evaluate colostral antibody status. An online survey of all Irish private veterinary practitioner clients of the RVLs gathered their opinions on the cause and impact of the event.

Results: There was an increase of 37,838 (31.4%) in the number of on-farm cattle deaths reported to the AIM database but this was not uniformly distributed across age categories. There was a 28% increase in the number of bovine carcasses submitted to RVLs, and a 35% increase in the number of ovine carcasses submitted. There were 8% fewer bovine foetuses but 47% more ovine foetuses submitted.

There was an increase of more than 15% in the number of submissions of faecal samples from calves affected by diarrhoea, with a marked increase

in the relative frequency of detection of rotavirus (from 40% to 66%) and a slight increase in the relative frequency of detection of Cryptosporidium (from 27% to 29%). The percentage of animals with a low ZST test reading (which is interpreted as a failure of passive transfer) increased from 24% to 53%. Deaths in sheep due to liver fluke (*Fasciola hepatica*) infestation increased.

Eighty seven (87) of the approximately 900 private veterinary practices (PVPs) that were invited responded to an online survey. An increase in the number of sick calves treated was reported by 58.6% of respondents. 47% of respondents said the response to treatment was worse in 2013 than in previous years, while 43.2%. Almost 80% (78.9%) of respondents reported that they had attended more recumbent cows in the spring of 2013. Reduced fertility was observed among autumn and spring calving herds. Liver fluke was observed as a particular issue for sheep. Almost 73% suggested veterinary knowledge transfer initiatives had a role in dealing with such problems in the future.

Conclusions: There was a significant increase in mortality among cattle in the first four months of 2013, compared to the corresponding period in 2012. The mortality in cattle seems to have been worst among animals sired by beef bulls. Poorer quality colostrum as a result of insufficient energy and crude protein in the diet of dry cows is likely to be a significant predisposing factor to increased disease and mortality among calves in the first month of life. Nutrition plays a pivotal role in the immune response and negative energy balance can contribute to immunosuppression. Such immunosuppression will predispose to increased disease and death.

P02-002-003

Italian on-farm welfare assessment protocol for dairy cows: results from the last 4-years activities

Francesca Fusi^{1,2}; Alessandra Angelucci^{1,2}; Valentina Lorenzi^{1,2}; Luigi Bertocchi^{1,2}

¹Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia Romagna (IZSLER), ²Italian National Animal Welfare Reference Centre (CReNBA), Brescia, Italy

Objectives: Over the last 10 years farm animal welfare has been of increasing interest for public opinion; consumers are very sensitive to how farm animals are reared and they are becoming more and more distrustful about farmers' practices. Challenge for scientific community and public institutions is to provide an objective tool for identifying if animal welfare is guaranteed or not. The Italian National Animal Welfare Reference Centre (CReNBA) based in the Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia Romagna (IZSLER) in Northern Italy is trying to meet this challenge applying an on-farm welfare assessment protocol for dairy cows.

Materials and Methods: The CReNBA dairy cow welfare assessment protocol is based on scientific findings from Welfare Quality Project®, European Food Safety Authority (EFSA) publications on risk assessment related to dairy cow welfare and draft regulation concerning cattle (Strasbourg revised version No 8, 09/2009). The method takes into account also some minimum legal requirements (Council Directives 98/58/EC and 2008/119/EC). It consists of both management- and resource-based measures (Area A-Management and personnel, 23 indicators; Area B-Structures and equipments, 29 indicators) and animal-based measures (Area C, 18 indicators) such as: avoidance distance, body condition score, cleanliness of animals, lameness, integument alterations, udder health, mortality rate (cows and calves),

mutilations. Each assessment parameter has three choice options: unacceptable (hazard), acceptable and excellent (benefit). Parameters have different weighted scores given by an expert opinion consultation, based on their importance in decreasing or improving animal welfare. The overall welfare score results from adding partial scores of each Area and is expressed on a scale 0-100%. The protocol has been checked for inter-operators agreement. Application of this protocol by a skilled operator takes about 2 hours in a 100-lactating-cows-herd. From 2012 to 11/2015, 1047 Italian dairy herds in loose housing system have been assessed for animal welfare by 104 veterinarians that attended a specific training course at CReNBA. Farms were selected all around Italy for research activities and private consultation purposes.

Results: Dairy herds were characterized by an average number of 252.7 animals (min 7-max 2736), 116.3 lactating cows (min 4-max 1135) and 27.9 kg/per cow as daily milk production (min 10-max 41). The recorded overall welfare scores (WS) ranged from 36.18% to 95.90%, and most of them were very high (first quartile: 63.84%; median: 70.42%; third quartile: 77.31%). Herds with overall WS under the median value (70.42%) were found to be smaller and less efficient in milk production compared to herds that gained a WS >70.42%: statistically significant differences were found in average herd size (234 vs 271 animals, respectively; P-value = 0.0049), average number of lactating cows (108 vs 124.5 cows, respectively; P-value = 0.0053) and average daily milk production (26.8 vs 29.02 kg milk per cow/day, respectively; P-value <0.001). There were positive Pearson correlations between partial scores given to Area C (animal-based measures) and Area A (indicators about managerial factors; $\rho = 0.446$) and Area B (indicators about structural factors; $\rho = 0.382$). Despite very good results on animal welfare assessment, most of the farms (52.05%) had at least one non-compliance with minimum requirements provided by the law in force, mainly for calves under 6 months of age: the most frequent non-compliances were absence of contact between calves in single cages (349 farms) and disbudding performed after 21 days of age (226 farms).

Conclusions: The CReNBA dairy cow welfare assessment protocol is a reliable, timesaving, repeatable and scientifically-based tool to evaluate animal welfare level on-farm. Data collected in 1047 dairy herds showed positive information about dairy cow welfare in Italy. Herds with higher welfare levels were found to have more animals and higher production, as dairy cows in good welfare conditions usually have better performances. A stronger correlation was found between managerial factors (Area A) and welfare consequences on cows (Area C) meaning that skilful stockmanship can have larger effects in promoting animal welfare than housing structures (Area B).

The effects of 6, 12, 30 or 48 hours of road transport on the physiology and behaviour of yearling beef cattle destined for a feedlot in Australia

Andrew Fisher¹; Caroline Lee²; Jim Lea²; Dominic Niemeyer²; David Paull²; Drewe Ferguson²

¹Faculty of Veterinary and Agricultural Sciences, The University of Melbourne, Werribee, ²CSIRO, Armidale, Australia

Objectives: In northern Australia, livestock can be transported by road over considerable distances and durations. Although industry experience suggested that healthy cattle adapted to local conditions tolerated such

transport well, the aim of this study was to quantify the impact of transport duration on behavioural and physiological indicators of cattle welfare, in yearling cattle transported under controlled conditions for 6, 12, 30 or 48 hours from farm to feedlot entry.

Materials and Methods: Composite *Bos taurus* x *Bos indicus* heifers (n=480; mean liveweight 383.5 ± 35.3 kg) were used for the experiment. The design comprised 4 transport duration treatments of 6, 12 and 30 and 48 h and these were replicated over 2 weeks. The cattle were transported from their backgrounding property to the feedlot using single trailer commercial trucks. The departure times were staggered to allow the trucks to arrive at the feedlot on the same day. On arrival, the cattle were allocated to pens with access to hay and water. Detailed measurements including liveweight, blood chemistry and haematology were collected on 15 focal animals on each vehicle (n=30 per treatment) pre-transport, immediately on arrival and 24 and 72 h after arrival. Rectal temperature was logged over the entire transport and 72 h post-transport phases. Behaviour was monitored over the immediate 6-7 h post-transport period for the 12- and 48-h transport treatments. After the 72-h recovery phase, the cattle were regrouped and finished in the feedlot over 43 days prior to slaughter.

Results: Blood variables were significantly altered by transport but generally remained within normal ranges. Blood urea nitrogen was elevated at 0 h compared with 24 and 72 h post-transport. Animals transported for 48 h in week 2 recorded the highest BUN after transport (22 mg/dL). Other hydration indicators- total protein and albumin were similar, with a decrease during the first 24 h post transport, and a duration × week × time interaction. Creatine kinase was increased following transport (694 U/L) and then declined over 72h, with no effects of transport duration. β-hydroxybutyrate was not increased by transport. Cortisol exhibited a significant transport duration × time effect. At unloading, cortisol was highest in animals transported for 48 h (93 nmol/L), followed by animals transported for 30 h (74 nmol/L), with animals from the 6- and 12-h treatments lower (~62 nmol/L) and not different from each other. In each case post-transport cortisol was lower than immediately prior to loading. Similarly, the combination of loading and initial stages of transport were the most stressful as indicated by a sharp rise in rectal temperature. There was positive trend between transport duration and liveweight loss however, the differences between the treatments were not always significant. The cattle recovered the majority (95 – 98%) of the weight lost through transport by 72 h after transport. Cattle transported 48 h spent significantly more time lying during the initial 3 h post-transport phase but not thereafter. Transport duration had no effect on feedlot average daily gain.

Conclusions: Although long-distance transport as practised by industry in northern Australia represents a physiological challenge for the animals, the data suggest that healthy cattle can respond and remain within acceptable physiological limits. The caveat is that these results apply to healthy, well-fed animals undergoing good practice handling and transport procedures. Cattle that are compromised by undernutrition, age or reproductive status, or by extreme climatic conditions, should only be transported if they are fit for the intended journey.

Heart rate, heart rate variability and fecal glucocorticoid metabolites of dairy cows before and after changeover to an automatic milking system

Viktor Jurkovich¹, Luca Fruzsina Kezer^{2,3}, Ferenc Ruff⁴, Margit Kulcsar⁵, Levente Kovács^{2,3}

¹Department of Animal Hygiene, Herd Health and Veterinary Ethology, Szent Istvan University Faculty of Veterinary Science, Budapest, ²MTA-SZIE Large Animal Clinical Research Group, Ullo, ³Institute of Animal Husbandry, Szent Istvan University Faculty of Agricultural and Environmental Science, Godollo, ⁴Department of Methodology, Hungarian Central Statistical Office, ⁵Department and Clinics of Reproduction, Szent Istvan University Faculty of Veterinary Science, Budapest, Hungary

Objectives: A better comprehension of animal stress is a key aspect in welfare assessment. Continuous monitoring of the tone of the autonomic nervous system helps to identify both the biological and the environmental elements of a stress situation. In dairy cows, the type of milking – notably the human presence and handling it involves – is considered to be one of the main influential factors. The aim of the study was to measure the effects of a newly installed automatic milking system (AMS) on the welfare – as reflected in the changes in the autonomic nervous activity – of the cows at a Hungarian dairy farm.

Materials and Methods: The study was performed on a small scale (80 lactating cows) dairy farm where the conventional 2x5 herringbone milking parlour was changed to a new DeLaval VMS type AMS. In the first study period (March), when the conventional milking system was in operation, 27 clinically healthy Holstein Friesian dairy cows (age: 4.8±1.6 yrs, parity: 2.6±0.5, days in milk: 213.3±36.4) were examined. In the second part of the study (May) the same animals were studied, 2 months after the changeover to AMS. In this latter period, data from 18 of the 27 animals were analyzed.

Heart rate (HR) was recorded using a Polar RS800 CX recording system (Polar Oy Kempele, Finland). During the conventional milking period, the HR monitors were fitted on the animals after the morning milking and recordings lasted until returning from the evening milking (approx. between 8 am and 7 pm). During the AMS period, the electrodes were attached in the morning hours and detached after a 24-hour recording session. The Kubios HRV software (University of Kuopio, Finland) was used for heart rate variability (HRV) analysis. The SD2/SD1, HF, LF/HF measures of HRV were calculated in the periods of 1) lying and standing in the barn, 2) prior to the milking (driving and waiting) and 3) during the milking (preparation, milking, waiting for exit). Fecal samples were taken from the animals in the morning and in the evening on the day they were monitored, for laboratory determination of glucocorticoid concentration by RIA method.

Results: HR and HRV parameters measured when the animals were in their barns, lying or standing, showed no difference before and after the changeover. There were, however, significant differences in all parameters measured in the time period when the animals were driven by the stockperson and waiting for milking in the parlour, compared to the 'self-driven' and relatively calmer waiting period at the AMS. Area under the curves (AUC) of heart rate (mean ± SE: 48.9±12.0 vs. 25.9±7.6 min⁻¹, P=0.0217), SD1/SD2 (14.8±3.9 vs. 0.6±2.49, P=0.0009), LF/HF (12.6±0.4 vs. 9.2±0.1, P=0.033) were higher, while HF was lower (-23.1±13.6 vs. -5.3±7.3 normalized unit, P=0.0245) indicating higher sympathetic tone in the pre-milking period in the parlour milking routine compared to the AMS. During the milking and the post-milking waiting period (which was very short in AMS) the AUC values of SD2/SD1 (9.4±3.8 vs. -2.9±2.6, P=0.0325), LF/HF (20.7±1.9 vs. 13.7±1.4, P=0.026) were higher, while HF was lower (-29.2±13.4 vs. -0.8±4.9 n.u., P=0.0145) indicating a higher sympathetic tone in the conventional milking period compared to AMS. The HR did not differ during and after milking. The fecal corticosteroid concentrations were significantly higher both at the morning (54.5±3.1 vs. 20.6±1.8 ng/g, P=0.0038) and at the evening (58.2±4.3 vs. 19.0±1.9 ng/g, P=0.0034) sampling during the conventional milking routine.

Conclusions: Periods of frequent interaction with humans – and especially rough handling – are potential sources of stress for dairy cows,

as shown by a higher sympathetic tone. Freedom of moving and being milked voluntarily can significantly improve animal welfare on farms with automatic milking systems.

P02-002-006

Comparison of mortality rates in different categories of cattle during transport for slaughter

Vladimir Vecerek¹, Veronika Simova¹, Eva Voslarova¹, Iveta Bedanova¹

¹Department of Veterinary Public Health and Animal Welfare, Faculty of Veterinary Ecology and Hygiene, University of Veterinary and Pharmaceutical Sciences Brno, Brno, Czech Republic

Objectives: The death of animals during transport for slaughter is a major factor indicating the standard of welfare in transported animals. The aim of this study was to determine the mortality rate in different categories of cattle transported for slaughter in the Czech Republic in the period from 2009 to 2014.

Materials and Methods: Data summarizing the numbers collected from all cattle transport movements in the Czech Republic in the monitored period were gathered in the database of the Information Centre of the State Veterinary Administration. The percentages of transport deaths out of the total number of cattle transported within each category were calculated. On the basis of these results, the differences in transport-related mortality rates between individual categories of cattle in each year and for the entire monitored period were evaluated. All the data were analysed using the statistical package Unistat v. 6.5. Statistical comparisons between the frequencies of the categorical variables of interest were performed with the Chi-square test (with Yates correction when needed) within the contingency table procedure. Data concerning transport-related mortality rates in individual cattle categories were compared between the individual monitored years and also the differences in mortality rates among cattle categories were tested for each year. Data concerning mean mortality rates in individual cattle categories for the entire monitored period in the study were compared by a Kruskal-Wallis one-way ANOVA and subsequently by a Tukey-type test with ranked sums as a post hoc test for pairwise comparisons.

Results: In the monitored period, in total 1,552,574 head of cattle were transported for slaughter, out of which 1,935 (0.125%) died as a result of this transportation. During the monitored period, the overall mortality rate of cattle transported for slaughter in the Czech Republic declined from 0.333% in 2009 to 0.030% in 2014, which is a positive finding. However, highly significant ($p < 0.01$) differences were found among the transport-related mortality rates of individual categories of cattle. The highest mortality rate was found in calves (0.296%), followed by dairy cows (0.207%) and feeders (0.058%), and the lowest mortality was found in fattened cattle (0.017%). The mortality rate in calves transported for slaughter ranged from 1.045% to 0.063% in individual years with a significant decrease ($p = 0.044$) in the last year. The transport-related mortality in dairy cows ranged from 0.548% to 0.051% in individual years of the monitored period. The values fluctuated significantly ($p < 0.05$) among individual years. When comparing mortality rates among individual cattle categories, significantly ($p < 0.01$) higher levels of mortality were found in calves and dairy cows than in fattened cattle and feeders each year. Higher mortality rates in dairy cows and calves may be related to the fact that dairy cows and calves are excluded from breeding usually due to decreased performance, which may result from the animal's poor condition. Together with transport-related stress, this

may become a critical factor leading to impaired health and finally to the death of an animal.

Conclusions: It is obvious from the results that the age and category of animals transported play an important role in terms of animal welfare during the transportation process. The statistics of cattle deaths may further improve if the requirements for animal welfare are strictly observed by farmers, hauliers and slaughterhouse operators and the observance thereof controlled by the relevant administrative bodies with an emphasis on categories that are at higher risk of experiencing poor welfare during transport.

Animal Welfare

P02-002-007

Temporal relationship between milk production and meteorological variables in southern Brazil

Alexandre M. Gabbi¹, Vanessa Peripolli², João Batista G. Costa Jr², Jaime A. Cobucci¹, Vivian Fischer¹, Concepta Mcmanus²

¹Animal Science, Federal University of Rio Grande do Sul, Porto Alegre, ²University of Brasilia, Brasilia, Brazil

Objectives: The objective of this study was to evaluate the relationship between meteorological variables and milk production over a 15 year period in Holstein herds in Castro region, Paraná State, southern Brazil.

Materials and Methods: Milk collection data were available for a 15 year survey period and included animal identification, herd, milk control date, calving date, lactation order, days in milk, animal age, daily milk production and milk production per lactation and meteorological data included precipitation, environmental temperature, air relative humidity, wind speed, solar radiation, Piché evaporation index, temperature and humidity index (THI) and temperature and humidity index corrected for solar radiation and wind speed (corrected THI). The total data set was composed by 161,351 milk control data measured as milk/cow/day and 10,162 meteorological information, collected during 15 years period. Data were subjected to correlation analysis (CORR) and multivariate statistical tests including principal components (PRINCOMP) and step-by-step (STEPDISC) analyses, using the Statistical Analysis System (SAS®).

Results: Average daily milk production was 30.57 L/cow, where 74.74% of cows produced between 20 to 40 L/day with 30.19% of cows in second lactation aged between 37 to 60 months and between 101-200 days in milking. In addition, 67.18% of cows were milked twice a day and 32.82% milked three times a day. The highest average maximum temperature recorded during the 15 year period of observations did not exceed 30°C and the temperature and humidity indexes were maintained within acceptable values for animal thermal comfort (THI between 64 and 68). Correlations between milk production and meteorological variables during 15 year period and according to the climatic seasons were low. Although the minimum and maximum temperature variables showed higher relationships with milk production when compared with other variables, they were not responsible for a marked change in the milk production. When extremes were observed in temperature or humidity associated with solar radiation and wind speed, such as in Summer and in Winter, the corrected THI was important as an indicator of climatic welfare of lactating cows, even though this variable was not seen to influence milk production.

Conclusions: In Summer and Winter seasons, the temperature and humidity index corrected for solar radiation and wind speed showed great

importance as an indicator of climatic welfare of lactating cows, even though this variable was not seen to influence milk production. The Castro region, Parana, Brazil has adequate weather for milk production from high performance European dairy breeds.

P02-002-008

Quantification of extended characteristics of locomotor behavior in dairy cows

Maher Alsaad¹, Joel Niederhauser², Gian Beer¹, Gertraud Schuepbach³, Adrian Steiner¹

¹Clinic for Ruminants, Vetsuisse-Faculty, University of Bern, Bern, ²InnoClever GmbH, Liestal, ³Veterinary Public Health Institute, Vetsuisse-Faculty, University of Bern, Bern, Switzerland

Objectives: The objective of this study was to develop and validate a novel algorithm to monitor locomotor behavior of loose-housed dairy cows based on the output of the RumiWatch® pedometer. It was hypothesized that a novel algorithm of the RumiWatch® pedometer device can be developed that provides a high correlation of parameters of behaviour of dairy cows in both upright and lying positions between the output data of the pedometers and the data derived from temporarily staggered video analysis.

Materials and Methods: Data of locomotion were acquired by simultaneous pedometer measurements at a sampling rate of 10 Hz and video-recordings for manual observation later. The study consisted of 3 independent experiments. Experiment I was carried out to develop and validate the algorithm for lying behavior, experiment II for walking and standing behavior and experiment III for stride duration and stride length. The final version was validated, using the raw data, collected from cows not included in the development of the algorithm. Spearman correlation coefficients (r_s) were calculated between accelerometer variables and respective data derived from the video recordings (gold standard). Dichotomous data were expressed as the proportion of correctly detected events, and the overall difference for continuous data was expressed as the relative measurement error (RME).

Results: In all experiments, the mean difference between accelerometer data and respective gold standard was between 0% and 17%, and the correlation between respective data ranged from $r_s = 1$ to $r_s = 0.75$. The proportions for correctly detected events or bouts were 1 for stand ups, lie downs, standing bouts, and lying bouts and 0.99 for walking bouts. The relative measurement error and Spearman correlation coefficient for lying time were 0.09% and 1; for standing time, 4.7% and 0.96; for walking time, 17.12% and 0.96; for number of strides, 6.23% and 0.98; for stride duration, 6.65% and 0.75; and for stride length, 11.92% and 0.81, respectively.

Conclusions: The strong to very high correlations of the variables between visual observation and converted pedometer data indicate that the novel RumiWatch® algorithm may markedly improve automated livestock management systems for efficient health monitoring of dairy cows.

Animal Welfare

P02-002-009

Effect of an intravenous injection of flunixin on stress related parameters in healthy dairy cows

Sandra Bertulat¹, Wolfgang Heuwieser¹

¹Clinic for Animal Reproduction, Freie Universität Berlin, Berlin, Germany

Objectives: Previous studies investigated the effect of non-steroidal anti-inflammatory drugs (NSAID) on stress and pain in cows with various disease by evaluating behavioral changes and measuring cortisol. The efficacy of NSAID to lower cortisol and reduce behavioral changes has been proven. However, it remains unclear how much the injection effected the stress parameters and if NSAID influenced cortisol only by reducing pain or by effecting the cortisol metabolism itself. Therefore, the aim of this study was to investigate the effect of a single injection of NSAID on fecal cortisol concentration and standing and lying behavior in healthy dairy cows.

Materials and Methods: Twenty-four healthy (i.e., without metabolic or infectious disease or lameness) Holstein-Friesian dairy cows were enrolled 14 – 21d after dry-off in a double-blind, placebo-controlled, crossover trial. Upon enrolment all cows were fitted with a HOBO Pendant G Data Logger (Onset Computer Corporation, Pocasset, MA) to continuously record standing and lying behavior in 1-min intervals. Daily time lying and number of lying bouts was calculated starting with the day after enrolment. Four days after enrolment (t0) cows were fixed in tie stalls and received an intravenous injection in the jugular vein of either NSAID (i.e., 2.2 mg/kg flunixin, 2ml/45kg Parafunixin RPS, Bayer Animal Health, Monheim, Germany) or placebo (PLA; i.e., 2 ml/45kg normal saline) based on a randomization list. Fecal samples were collected to measure fecal cortisol metabolites (i.e., 11,17 dioxoandrostanes; DOA). DOA measurement is a well-established and feedback free method (i.e., minimal stress due to restraining and handling) to quantify stress in cows. Fecal samples were obtained from the rectum before treatment (t0) as well as 24, 36, 48, 60, 72 and 96h after treatment and frozen at -26°C till analysis. DOA was measured utilizing an 11-oxo-etiocholanolone enzyme immunoassay. 1 wk after first treatment cows received an injection of the substance that was not used in the 1st study week. Fecal samples were again collected on t0, t24, t36, t48, t60, t72 and t96.

Data were analyzed utilizing a generalized linear mixed model. Time after treatment was included as repeated factor and cows as random effect.

Results: Baseline DOA on t0 did not differ between 1st and 2nd study week (93.2 ± 38.4 ng/g; $P = 0.256$). While there was no difference between NSAID and PLA treated cows ($P = 0.284$), DOA concentration in all cows increased between 24 and 36h after injection (115.5 ± 51.8 ng/g; $P = 0.009$) and remained on an elevated level until 72h (111.7 ± 59.1 ng/g) after injection ($P > 0.05$). DOA baseline levels of t0 and t24 DOA were reattained 96h after injection ($P > 0.05$). Time lag between injection and an increased DOA level was consistent with previous studies that described a minimum of 8 to 16 h between an increase in blood cortisol coinciding with the stressor and an elevated concentration of fecal DOA. There was no effect of week (i.e., 1st or 2nd study week; $P = 0.997$) or parity ($P = 0.692$) on DOA concentration.

Before treatment average daily time lying was 750 ± 170 min with an average of 8.7 ± 3.6 lying bouts. On the day of injection average daily time lying decreased to 669 ± 165 min ($P = 0.003$) with an average number of lying bouts of 8.0 ± 3.2 ($P = 0.039$). Total time lying and the number of lying bouts reattained baseline values 1 day after injection and remained on these level throughout the study. While there was no effect of treatment (i.e., NSAID or PLA; $P = 0.241$) and study week ($P =$

0.707) on daily time lying, an interaction between parity and time relative to treatment was found ($P = 0.06$). Cows in 3rd or higher lactation lay 98 min less on the day of injection compared to the days before and after ($P < 0.001$). There was no effect in 1st or 2nd lactation cows ($P > 0.05$).

Conclusions: NSAID have no effect on cortisol metabolism in healthy dairy cows and do not influence standing and lying behavior. While a single intravenous injection and the associated fixation of the cows effect standing and lying behavior on the day of treatment, fecal glucocorticoid metabolites remain elevated up to 72h after injection. Further studies are necessary to investigate, why standing and lying behavior on the day of injection was only affected in older cows.

Animal Welfare

P02-002-010

Prevalence of production diseases in European organic dairy herds

Margret Krieger¹, Karin Sjöström², Ulf Emanuelson², Isabel Blanco Penedo³, Julie E. Duval⁴, Aurélien Madouasse⁴, Nathalie Bareille⁴,
⁵Albert Sundrum¹

¹University of Kassel, Witzenhausen, Germany, ²SLU, Uppsala, Sweden, ³IRTA, Monells, Spain, ⁴Oniris, LUNAM Université, ⁵INRA, Nantes, France

Objectives: Despite decades of research and efforts in cattle herd health, production diseases remain a serious problem in modern dairy operations. They compromise the welfare of cattle and result in severe economic losses. Organic farming aims at good animal welfare and seeks to realise that aim by setting minimum standards for housing, feeding and management. The purpose of this study was to determine the prevalence of production diseases in organic dairy herds in four European countries.

Materials and Methods: Data from organic dairy farms that took part in the IMPRO project (impro-dairy.eu) were analysed. All farms were visited once in 2013 for the assessment of general characteristics, resources, and management procedures. A specifically designed on-farm protocol was administered during the visits which included a face-to-face interview with the person in charge of herd health management. A representative sample of the lactating cows was scored for lameness according to the Welfare Quality[®] protocol for dairy cattle. Data from the national milk recording systems and animal movement databases were retrieved according to the specifics in each country. All records were transformed into a common data structure and analysed using a common R script. Herd prevalences were calculated using sets of herd-level indicators related to udder health, metabolism, reproduction and lameness. Subclinical mastitis (SM) was diagnosed if composite milk samples were above a somatic cell count of 100 000 cells/ml. Risk of ketosis (KET) was defined as a fat-to-protein ratio > 1.5 during the first 100 days of lactation. Risk of subacute ruminal acidosis (SARA) was defined as milk fat percentage < 3.0 after 30 days in milk. In terms of reproductive performance, the prevalence of prolonged calving intervals (PCI) > 400 days was calculated. Overall lameness (OL) prevalence was obtained by adding up moderate and severe lameness prevalence.

Results: The study enrolled a total of 192 farms, with 60, 23, 54 and 55 in Germany (DE), Spain (ES), France (FR) and Sweden (SE), respectively. Within the whole group the time since conversion to organic farming ranged from under 1 to 29 years with a median (m_{ALL}) of 7. Herds were largest in SE (m_{SE} 68.1 cow-years) and smallest in ES (m_{ES} 29.7) ranging from 7.4 to 376.5 cow-years. In all countries all lactating cows

had access to pasture except for DE where 23% of farms only provided an outdoor run. In 69.8% of all farms cows were kept in loose housing with cubicles. Automatic milking systems were used by 10% of farms in DE and 49.1% in SE, and not at all in ES and FR. On animal-level the predominant breeds across countries were Holstein (48.2%), Red Dairy Cattle (15.6%), and Simmental (9.9%). Milk yield varied between countries. The median energy-corrected yields were 6588, 5742, 6378, and 8979 kg in DE, ES, FR and SE respectively (range_{ALL} 2324 – 10 880 kg). Herd prevalence of SM ranged from 18.9 to 94.2% and was lowest in SE (m_{SE} 44.1%) and highest in ES (m_{ES} 57.5%). KET prevalence was lowest in ES (m_{ES} 6.2%) and highest in DE (m_{DE} 11.4%) ranging from 0 to 45%. Prevalence of SARA was lowest in SE (m_{SE} 2.2%) and highest in ES (m_{ES} 14.8%) with a range of 0 – 42.3%. PCI ranged from 4.4 to 90.5% and was highest in ES (m_{ES} 62.5%) and lowest in DE (m_{DE} 36.3%). Median prevalence of OL was 20.4%, 10%, 23.2%, and 4.17% in DE, ES, FR, and SE, respectively (range_{ALL} 0 – 79.3%).

Conclusions: In terms of production diseases there is a large variation amongst organic dairy farms in Europe with a considerable proportion of farms not meeting the aim of good animal health and welfare. This leads to the conclusion that process-related minimum standards for organic animal husbandry cannot be regarded as effective in that respect. One major achievement of this study was the description of the status quo on the basis of extensive data and harmonised methods. The results call for new, improved strategies to achieve outstanding animal health and welfare in organic dairy systems.

Comments: This project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement n° 311824 (IMPRO).

Comparison of efficacy and onset of intravenous regional and nerve block anesthesia in the distal hind limb of dairy cows

Samaneh Yavari¹, Nimer Khraim², György Szura¹, Alexander Starke³, Elisabeth Engelke⁴, Christiane Pfarrer⁴, Klaus Hopster⁵, Sabine Kästner⁶, Juergen Rehage¹

¹Cattle Clinic, University of Veterinary Medicine Hannover Foundation, Hannover, Germany ²Department of Surgery and Anesthesiology, Nablus University, Nablus, Palestinian Territory ³Clinic for Ruminants, Leipzig University, Leipzig ⁴Department of Anatomy, University of Veterinary Medicine Hannover Foundation, Hannover, Germany ⁵Clinic for Horses, University of Veterinary Medicine Hannover Foundation, Hannover, Germany ⁶Clinic for Small Animals, University of Veterinary Medicine Hannover Foundation, Hannover, Germany

Objectives: Claw lesions leading to lameness are frequent health disorders in dairy cows and require commonly surgical correction for treatment. As part of a pain management protocol, local anesthesia is necessary for such surgical interventions. Although, intravenous regional (IVRA) and nerve block anesthesia (NBA) are described in textbooks the efficacy and onset of these two techniques are not yet evaluated in dairy cows. Therefore, efficacy and onset of anesthesia in the distal hind limb after IVRA and NBA were tested by means of pain stimulation techniques.

Materials and Methods: Six healthy, non-lactating, non-pregnant German HF cows were used in a cross-over design study. In all cows IVRA and NBA were tested in lateral recumbency on a surgical tipping table. For

IVRA, 20 ml procaine (Procasel 2%, WDT, Germany) were injected into the V. digitalis dorsalis communis III or V. digitalis lateralis communis IV after application of an esmarch bandage in the metatarsal region. NBA was performed at four sites using about 15 ml procaine at each site (A: Superficial Fibular Nerve: directly beneath the skin subcutaneously at the dorsal hind leg proximally to the hock joint, B: Deep Fibular Nerve: at the dorso-medial surface of metatarsus inside the proximal region of the groove, C: Medial Plantar Metatarsal Nerve: at the middle of medial metatarsus preneurally above the superficial flexor tendon and D: Lateral Plantar Metatarsal Nerve: at the middle of lateral metatarsus preneurally above the superficial and deep flexor tendons). Anaesthesia was tested by assessment of thresholds of I) Electrical stimulation (Grass S48 Square Pulse Stimulator) at the dorso-lateral coronary band as well as soft skin of heel, and II) Mechanical pressure stimulation at the lateral and medial sites of the bulb of heel, flexor tendon and fetlock joint. Stimulation was performed before (control) and 5, 7.5, 10, 12.5, 15 and 20 min after anesthesia. Reaching of the threshold level was assumed when first, slight responses on stimulation such as claw movements were recognized. One cow was excluded from statistical evaluation, because 20 min after anesthesia electrical stimulation revealed no complete onset of anesthesia. Results were statistically evaluated by ANOVA for repeated measurements (SAS package Vers. 9.3).

Results: Before anesthesia reaction thresholds for electrical stimulation were in average 37 V (+/- 9, range 25 - 60) and for pressure stimulation 17 N (+/- 4, range 9 - 20). Twenty min after anesthesia in statistically evaluated cows, tested thresholds reached the preset maximum level of 150 V and 20 N for electrical and pressure stimulation, respectively.

However, the excluded cow showed after IVRA no reactions on pressure stimulation at 20 N but reacted on electrical stimulation at 120 V. After NBA all evaluated cows reached the maximum preset levels of electrical pain stimulation after 12,5 min at the heel and after 10 min at the coronary band. Maximum stimulation levels were reached not before 15 min after IVRA which was significantly delayed compared to NBA cows (group and group * time interaction effects $p < 0.05$).

Conclusions: IVRA and NBA lead generally to anesthesia in the distal hind limb of dairy cows. Because in one cow IVRA failed to induce full anesthesia, efficacy of both techniques need to be tested in a larger number of cows. Onset of anesthesia in the distal hind limb of cows is significantly delayed after IVRA compared to NBA. Surgical treatments of claw lesions in the field are commonly performed under time constraints. Therefore, the delay in the onset of anesthesia after IVRA may have practical relevance in the view of animal welfare, when surgical interventions are executed before full onset of anesthesia is achieved.

Monitoring welfare in practice on Dutch dairy farms

Frank Van Eerdenburg¹, Bert Snel², Jan Hulsen³, Arjan Stegeman¹

¹Dept Farm Animal Health, Faculty of Veterinary Medicine, Utrecht,

²DLV - Advies, Deventer, ³Vetvice, Bergharen, Netherlands

Objectives: The Welfare Quality welfare assessment protocol[®] (WQ) is quite intensive and it takes a long time (up to a day) to assess a farm. Several other protocols have been designed and published that do not require a full day for a single farm. These have been compared with WQ. This in order to come to a less time consuming protocol that has a similar

outcome. This is important because an increase in welfare is correlated with a higher milk yield (Van Eerdenburg et al., 2013).

Materials and Methods: In this project 3 other welfare measuring protocols: Welzijnswijzer (=Welfare Indicator), Koekompas (=Cow Compass) and the Continue welzijns monitor (=Continuous Welfare Monitor), have been compared with WQ on 60 dairy farms in the Netherlands. Four veterinary practices made a list of their dairy farmer clients. Each was given a score from good to bad, based on the availability of good quality food & water, quality of housing, health and behaviour. Out of the lists, randomly, 60 farms were selected in such a way that in each practice there were 5 good-, 5 average- and 5 bad farms. The farms were visited within 2 weeks for all protocols in order to avoid changes in welfare status over time. The result of the WQ protocol was considered to be the reference and the other three were correlated with WQ (Pearson correlation in SPSS version 20.0). Not only at the level of the end score, but also at principle, criteria and indicator level.

Results: The results for WQ were: 3 farms with score Not Classified, 52 with score Acceptable and 5 Enhanced, no farm was scored Excellent. This implies that WQ does not have a proper discriminative capacity. Because of this, the correlations with the other protocols were very low and not statistically significant. In relation to the WQ endscore the Pearson correlation was calculated for the principle of Feeding 0.46; Housing 0.15; Health -0.07 and Behavior 0.47. Therefore, the original WQ was adapted in 3 ways: 1) Drinkers: If one of the drinkers is dirty, all drinkers are considered to be dirty. In the adapted protocol, therefore, a weighted score for cleanliness was introduced. A clean drinker scored 1, partially dirty 2 and dirty 3 points. The total for drinkers is divided by the average score for the cleanliness. 2) Integument alterations: The average number of HP, lesions and swellings per cow is used in the calculations. 3) Qualitative Behaviour Assessment (QBA): The QBA is seriously disputed (Bokkers et al., 2012) and, in the experience of the present study, very difficult to explain to the farmers. With the use of the QBA, farmers are not convinced that the result is something to be taken seriously. Therefore, the QBA was omitted.

A new score was calculated for the 60 farms: 22 farms scored Not Classified, 31 scored Acceptable and 7 Enhanced, no farms scored Excellent. The Pearson correlations of the 4 principles were: Feeding: 0.85; Housing: 0.45; Health: 0.99 and Behaviour: 0.99.

Conclusions: Assessing welfare of a group of animals can be done with animal based measures and environmental measures. Animal based measures, like behavior, reflect better what the status of the cow is, but need a substantial amount of time to assess, whereas measuring the environment can be done relatively fast. For some parameters there was a high correlation between the animal based and environmental measures.

It is proposed to change the WQ protocol according to the 3 adaptations described above. The newly developed protocol can be used as a screening tool for welfare problems and to improve the management on a dairy farm.

Pre – Slaughter Assessment of the Welfare of Livestock at Three Abattoirs in Northern Nigeria

Mohammed Sanusi¹, Shehu M. Ladan¹, Onuku I. Aisha², Hassan M. Mai¹, Bello Mohammed³

¹Department of Animal Production, Abubakar Tafawa Balewa

University, Bauchi, ²Department of Livestock and Veterinary Services,

Ministry of Agriculture, Lafia, ³Department of Veterinary Public Health and Preventive Medicine, Ahmadu Bello University, Zaria, Nigeria

Objectives: In Nigeria, most cattle are reared under extensive system in rural areas and spend long time in transportation between farms, market and slaughter places. Lack of good roads and poor transport system, have increased the difficulties of transportation of livestock in the country. Due to lack of trained personnel, animals are subjected to varying degrees of cruelty which have severe consequences on animal welfare, leading to reduction in meat quality. This study was conducted in order to evaluate the potential effects of pre-slaughter operations on welfare of animals at three municipal abattoirs in northern Nigeria.

Materials and Methods: Three municipal abattoirs in Bauchi, Kaduna and Nasarawa States in northern Nigeria were visited twice weekly for 12 months (May, 2013 – June, 2014). The operations considered include supply chain of animals, distances traveled, transit time, body condition score, and effect of trekking on physiological parameters of the animals slaughtered. Prevalence of bruising using gross assessment was determined in cattle, sheep and goats slaughtered. A pretested questionnaire was administered randomly to 150 animal health officers, livestock transporters and other personnel responsible for handling and inspection of animals at the three abattoirs. Blood samples were collected for haematological analysis from 50 each of cattle, sheep and goats during the slaughter period. Physiological parameters of cattle that trekked for 37 km to Lafia abattoir were measured.

Results: The result indicated that animals slaughtered at the three abattoirs were supplied from 21 different sources. Over 83% of all the animals slaughtered were goats in Bauchi and Lafia and 41% in Kaduna municipal abattoirs. Many of these animals have traveled distances of about 500km and spent up to 7 hours on transit. It was noticed that there were no appropriate loading facilities and animals are forced down from vehicles. It is worthy to note that the vehicles used were not designed for animal transport. Presence of abattoir equipment was only available at the Kaduna abattoir. Assessment of BCS showed that 4.2% of all the cattle slaughtered were emaciated, 26.1% moderate and 38.7% obese. Similar trend was observed in sheep and goats. There was poor knowledge of animal welfare among most of the personnel interviewed. The average prevalence of bruising in cattle, sheep and goats were 13.03 ± 0.20 , 10.66 ± 3.72 and 10.83 ± 1.76 respectively. Greater percentages of bruising were recorded on animals that traveled up to 100 km and above. There was no significant difference in PCV and Hb values between male and female cattle, sheep and goats slaughtered at Lafia and Bauchi abattoirs. However, there was a significant ($P < 0.001$) variation in blood parameters of male and female cattle and sheep slaughtered in Kaduna abattoir. There were also significant ($P < 0.001$) differences in body temperature and pulse rate in both male and female cattle before and after 37 km trekking.

Conclusions: Poor transport system; lack of abattoir infrastructure and lack of trained workers were identified as existing problems compromising animal welfare in the study area. It is therefore recommended that further research work concerning both transport and handling of livestock be conducted in a larger scale in Nigeria. This will be helpful in identifying solutions to the torment of animals during transport and at the abattoirs and the general improvement of animal welfare in Nigeria.

Impact of meloxicam administration in cows prior to caesarean on the efficacy of transfer of passive immunity in calves

Raphaël Guatteo¹, Caroline Lesort¹, Denys Durand², Gwénola Touzot-Jourde³

¹UMR 1300 Oniris & INRA BioEpAR, Nantes, ²UMR INRA 1213 Herbivores, Theix, ³Surgery – Anesthesia Unit, Oniris, Nantes, France

Objectives: Some authors suggest that in case of clinical signs of reduced vitality, it is plausible that providing NSAID to calves could improve the time to standing and increase colostrum intake and therefore decrease the risk of failure of passive immune transfer. The objective of the current study was to assess the benefit of meloxicam prior to caesarean to cows on the efficacy of transfer of passive immunity under the assumption that providing analgesia on the dam could lead to an earlier or longer colostrum intake by its own calf.

Materials and Methods: The study was performed in Burgundy in France in 2 veterinary practices. 48 Charolaise's cows were included in the study. Each cow was randomly allocated and was either treated with meloxicam subcutaneously (0,5 mg/kg) (n=22) or received no analgesia (n=26) prior to caesarean. Classical left flank approach with local anaesthesia was used for each cow. For each cow, colostrum quality (based on Brix refractometer), delay between the end of the caesarean and the first spontaneous colostrum suckling (based on farmer observation) and the IgG content in the sera (based on Radial Immuno Diffusion) of their calf 24 hours after birth of cows were analysed. In a first step, univariate analysis was done to compare the similarity of the cows within the 2 groups (colostrum quality, delay before first suckling). In a second step, the level of IgG was compared between treatment groups using chi-square test. In a last step, a logistic regression was performed to explain the level of IgG (below or above 15 g/L) according to the treatment group, the parity of the dam, the quality of the colostrum and the delay before first suckling.

Results: No significant differences were observed in the quality of the colostrum nor in the delay between the end of the surgery and the first spontaneous suckling of the calf between treatment groups. However, the number of calves showing a better transfer of passive immunity (IgG content >15g/L) was significantly higher among those originating from dams receiving meloxicam prior to caesarean. The results of the final logistic regression models indicated that the probability for a calf for having an efficient passive immunity transfer (>15 g/L) was significantly higher for calves born from a dam receiving meloxicam ($p=0.03$; OR=3.88 [1.01-14.96]) and for calves who suckled their dam within the first hour after birth vs > 4 hours ($p=0.02$; OR=5.90 [1.12-31.15]).

Conclusions: This original study confirms that pre-emptive analgesia in cows prior to caesarean leads also to a benefit for its own calf through an improved colostrum intake ensuring a more efficient transfer of passive immunity crucial for its short and long term survival. Additionally, this study confirms the crucial role of an early colostrum intake.

Comments: This work was supported by the Groupement Technique Vétérinaire de Bourgogne and by a grant from ICSA, the French Carnot Institute for Animal Health (<http://www.instituts-carnot.eu/en/carnot-institute/icsa>). We thank all the farmers for their invaluable help and cooperation.

P02-002-015

Interim results from a large-scale lameness prevalence study in Irish dairy herds.

Riona Sayers¹, Raphaelle Courson¹, Siobhan Ring¹, Alan Twomey¹, Ana Martinez-Ibeas¹, Noel Byrne¹, Eoghan O'Brien¹, Donagh P. Berry¹

¹Animal & Biosciences, Teagasc, Moorepark, Fermoy, Co. Cork, Ireland

Objectives: The majority of Irish dairy cows are maintained in a pasture-based system. Paddocks are grazed in rotation and cows walk to and from milking twice daily. Abolition of EU milk quotas has led to increased herd sizes, enlargement of grazing platforms and an increase in the distances cows walk for milking. Existing research indicates that longer walking distances predisposes dairy cows to hoof disorders. The objectives of this study were to (i) document the prevalence of mobility abnormalities and foot lesions in a large population of dairy cows, and (ii) investigate associations between mobility scoring and the presence of a foot lesion.

Materials and Methods: In November 2014, 69 spring-calving pasture-based dairy farms in the Munster area of Ireland were recruited to the HealthyGenes project. The total number of cows available for study was 11,380 of varying breed (Holstein-Friesian, Jersey, Norwegian Red). All cows were mobility scored (MS) using the DairyCo four point scale (<http://www.dardni.gov.uk/dairyco-scoring-chart.pdf>) on two occasions (spring and autumn) by two assessors scoring to a consensus. Mobility score was dichotomised for statistical analysis; cows recording a MS of 0 or 1 were categorised as 'none or minor mobility impairment' and those recording a MS of 2 or 3 were categorised as 'moderate to severe mobility impairment'. Hoof-trimming was also completed on over 6,000 cows and each individual categorised on the basis of how many lesions were simultaneously present (e.g. 0, 1, 2, 3 etc.). Lesions were identified using the ICAR Claw Health Atlas (http://www.icar.org/Documents/ICAR_Claw_Health_Atlas.pdf).

Descriptive data were coded and analysed in Excel (MS Office 2010). All statistical analyses were completed in Stata version 12 (StataCorp, USA). Univariable logistic regression was used to examine associations between MS in spring and MS in autumn, MS and the presence of at least one hoof disorder, and MS and the number of foot lesions present. Foot lesions were characterised as mechanical (e.g. white line disease, bruising, ulceration) or infectious (e.g. digital dermatitis, infectious pododermatitis). The severity of each lesion was also recorded but was outside the scope of the current analysis.

Results: Interim data from 46 herds were available for this analysis. In spring, 4% of all cows recorded MSs of two or greater. The prevalence of moderately to severely lame cows increased significantly to 6.7% in autumn ($P=0.0004$). Regression analysis highlighted that cows in autumn were almost 10 times more likely ($OR=9.83$; $CI=7.43, 13.02$; $P<0.0001$) to record a MS of two or greater compared to spring. In both spring and autumn, cows with multiple lesions were more likely to record a MS of two or greater. Cows recording five simultaneous lesions were over four times more likely to have a higher MS than those with no foot lesion ($P<0.0001$). Cows with a MS ≥ 2 were over three times more likely to have at least one foot lesion than cows with a lesser MS ($P<0.0001$). Mechanical lesions ($n=9413$) were more highly prevalent than infectious lesions ($n=156$). Bruising, white line disease and overgrown digits were the most common lesions recorded.

Conclusions: The prevalence of moderate to severe lameness in the Irish dairy system compares favourably with more intensive, indoor systems internationally. The increased prevalence of cow lameness in autumn, however, is a cause for concern, and most likely reflects the cumulative effect of daily road walking as the lactation progresses. The

greater number of mechanical rather than infectious lesions recorded in this study lends support to this theory. Although infectious causes of lameness require on-going prevention, we suggest that roadway/yard design and maintenance should form the basis for lameness control programmes on Irish dairy farms.

Haematology, Serum Glucose And Some Biomarkers Of Inflammation Of Some Domestic Ruminants' Lameness In Ibadan, Southwestern Nigeria

Olaekan Taiwo Lasisi¹, Olugbenga D. Babajide¹

¹University of Ibadan Nigeria, Ibadan, Nigeria

Objectives: In Nigeria, lameness is not yet identified as much welfare problem and as such there is scarce information on its effects on haematology, levels of serum glucose and measures of inflammatory reaction in domestic ruminants. This study was therefore aimed at investigating the effects of lameness on the haematology, serum glucose levels and some biomarkers of inflammation in some lame cattle, sheep and goats in Ibadan, South western Nigeria. The study was carried out in various settlements such as cattle and small ruminants markets, few households and Veterinary Teaching Hospital University of Ibadan Nigeria.

Materials and Methods: The domestic ruminants randomly sampled included 1500 cattle, 300 sheep, and 2200 goats of various breeds having estimated ages ranging between 8 months to 6 years, using the method of dentition. The study was carried out over a period of one year (2013-2014). Whole blood and serum samples were collected when the clinical signs of lameness were obvious and assessed by visual locomotion scoring of ≥ 3 and all causes of the condition diagnosed in each ruminant. The haematological parameters (Packed Cell Volume, Red Blood Cell Count, Haemoglobin Concentration, Mean Corpuscular Volume and Mean Corpuscular Haemoglobin Concentration) were determined using standard laboratory techniques with calculations. C-reactive protein (CRP), Tumour Necrosis Factor (TNF- α) and levels of Interleukins 1 and 6 (IL 1 and 6) were determined using Water's 616/626 High Performance Liquid Chromatography system while the serum glucose and Serum Amyloid A (SAA) levels were determined using Technicon's rapid colorimetric wave auto-analyzer II system. All data obtained was analyzed using descriptive statistics and SPSS statistical package version 9.0 at a significance level of 5%.

Results: Infectious and traumatic conditions appeared to be the most common causes of lameness in the three species of domestic ruminants; males tended to be more predisposed to lameness than their female counterparts in all the three ruminant species. Adult cattle and goats tended to be more predisposed to lameness but lambs seemed to be more predisposed among sheep. Most erythrocyte parameters which were significantly ($P<0.05$) decreased in lame cattle and goats were not significantly ($P>0.05$) different in lame sheep compared to normal values. There were significant ($P<0.05$) changes in the total and differential leucocyte parameters in the three species of lame domestic ruminants. All the selected inflammatory biomarkers (CRP, SAA, TNF- α , IL1 and IL6) were significantly ($P<0.05$) increased while the serum glucose level was significantly ($P<0.05$) reduced in the lame cattle, sheep and goats compared to the apparently healthy animals.

Conclusions: Therefore, Nigerian ruminant farmers and owners are now aware that lameness is a problem among all domestic ruminants with mechanical and infectious causes having deleterious effects on

adult large ruminants and goats. The increased inflammatory reactions and hypoglycemia in affected domestic ruminants are highlighted.

Comments: Key words: Haematology; Serum Glucose, Biomarkers of Inflammation; Domestic ruminants

Animal Welfare

Physiological and hematological parameters of cattle

Luiza Seixas¹Caio Cardoso¹Cristiano B. de Melo¹Candice B. Tanure¹Vanessa Peripolli¹Paulo Ricardo M. Lima¹Concepcion McManus¹*

¹University of Brasilia, Brasilia, Brazil

Objectives: Reference values used in tropical and subtropical regions are based on cattle raised in temperate climate and those in Brazil are subject to different environmental stressors. Therefore, the aim of the present work was to define reference values for blood and physiological parameters for cattle in Brazil.

Materials and Methods: A database with 355 observations of cattle in the South, Midwest and Northeast region of Brazil with information on time of day, breed, physiological and hematological characteristics and environmental variables. The Temperature and Humidity Index (THI) was calculated based on the climatic data at the time of each experiment using the following equation according to Thom (1959): $THI = \frac{1}{16} TDB + \frac{5}{8} TWB + 1.46$; Where: TDB = Dry Bulb Temperature (°C); TWB = Wet Bulb Temperature (°C);

The environmental condition was classified according to the level of stress and was considered stressful THI above 70 and not stressful THI at or below 70 (Hahn et al. 2009). For the calculation of mean hematology and physiological parameters only animals that were not stressed (332 observations) were considered.

The physiological and blood characteristics evaluated included: rectal temperature (RT), respiratory rate (RR), heart rate (HR), packed cell volume (PCV), total plasma protein (PPT), number of red blood cells (RBC), hemoglobin concentration (HB), mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC), number of white blood cells (WBC), monocytes (MONO), lymphocytes (LYMP), eosinophils (EOSI), segmented neutrophils (SEGM), platelets (PLAT).

Statistical analysis was performed using SAS® (Statistical Analysis Institute, Cary, North Carolina) with significance level of 5%. The procedures used included averages, confidence interval of 95% (pctlpts command in PROC UNIVARIATE) and frequency (PROC FREQ) to determine the number of observations outside the confidence interval (<2.5% and >97.5%).

Results: Most of the means of the studied parameters were within reference values. However, the values of 2.5 and 97.5 percentiles, which indicate the lower and upper limits, respectively, differed from those previously established in the textbooks. Heart rate was the parameter showing highest divergence, with mean (65.62 beats/minute) and maximum (116 beats/minute) values far above normal range (36-60 beats/minute) for cattle. The mean rectal temperature (39.02°C) was within reference interval (36.7-39.1°C), however the confidence interval (95%) ranged from 37.6 to 41.3 movements/minute and 121 observations were higher than the reference values. Mean respiratory rate (46 movements/minutes) was also within reference interval (26-50 movements/minute), but confidence interval (95%) varied from 40 to 116 movements/minute with 87 observations higher and 25 lower than pre-established values.

Regarding blood parameters, all means were within reference intervals, however there were divergences concerning the upper and lower limits. Mean PCV was of 35.56% with confidence interval of 20.4 - 47.0% and 58 observations were lower and 11 higher than reference interval (24.0-46.0%). The number of red blood cells ranged from 4.43 to 12.15g/dl and 32 observations were higher and 58 lower than reference interval (5.0-10.0g/dl). Thirty five observations of hemoglobin concentration were higher and 41 lower than reference values (8.0-15.0g/dl), with mean of 12.0g/dl. MCHC confidence interval was of 24-45.25% and 192 values were lower and 58 higher than reference interval (30.0-36.0%).

Conclusions: Means of all parameters, with exception of heart rate, were within textbook reference ranges for cattle; however, the upper and lower limits of many variables were different from the reference values, with significant number of observations outside reference interval. Therefore, considering that physiological and blood parameters are essential to evaluate pathological disorders, animal welfare and adaptability to the environment, the use of reference values based on animals subjected to similar environmental conditions is recommended for a correct interpretation of the results.

P02-002-018

Risks to cow welfare in an expanding pasture-based dairy industry – veterinary, advisory and farmer perspectives

Joanna Marchewka¹John F. Mee¹Laura Boyle¹

¹Animal and Grassland Research and Innovation Centre, Moorepark, Teagasc, Fermoy, Co.Cork, Ireland

Objectives: Cows in pasture-based systems of milk production generally have better welfare than those in confinement systems. However, abolition of the EU milk quota and subsequent intensification in the dairy industry may pose threats to cow welfare in pasture-based systems. ProWelCow (DAFM RSF-14/S/890) is a project which aims to investigate strategies to protect and improve the welfare of Irish dairy cows. This study aimed to identify areas of consensus and disagreement between stakeholders on the main risks to cow welfare associated with herd expansion to better understand the potential role of knowledge transfer in addressing cow welfare issues.

Materials and Methods: A questionnaire of approximately 40 questions was developed, tested and modified accordingly in conjunction with Teagasc dairy research and specialist advisory staff. The survey was conducted in 2015 with dairy farmers (F; n=115) at two national farming events (The National Ploughing Championships and the Moorepark Open Day) and cattle veterinarians (V; n=60) at the Cattle Association of Veterinary Ireland Conference by interview. The survey was distributed amongst Teagasc dairy advisors (A; n=48) at the beginning of an in-service training day where they were asked to complete the survey themselves. The 223 respondents were asked to identify the main welfare issue in Irish dairy cows from the following list: lameness, social stress due to overcrowding (SS), mastitis, metabolic disorders, infectious diseases, poor body condition score (BCS), cold stress and calving difficulties. The results are expressed as a percentage (%) of each group surveyed. A Chi-Square test for equality of two proportions (statistic: X²) was used to investigate whether distributions of response frequencies for the most important cause of poor welfare differed between surveyed groups using PROC FREQ in SAS.

Results: Poor BCS and SS were the 1^o welfare problems according to

22.6% and 14.8% of F, respectively. Of V, 30% selected SS and 28.3% selected lameness as the 1^o welfare issues. SS was selected as the 1^o welfare issue for Irish dairy cows by 46.7% of A and issues around calving by 20% of A. Poor BCS was ranked as the 1^o welfare issue for dairy cows by a higher proportion of F (72.2%) than of V (13.9%) or A (13.9%), ($P < 0.001$). There was good consensus between stakeholders on SS as an important welfare issue with 30.4% of F, 32.1% of V and 37.5% of A reporting it as the 1^o issue ($P > 0.05$). This is supported by the finding that 32.9% of farmers surveyed provided less than one cubicle per cow during the housing period. There was good agreement between F and V as to the importance of lameness to dairy cow welfare (45.5% and 51.5% reported it as the 1^o cause of poor welfare, respectively, $P > 0.05$). However, between the 3 groups, lameness was not recognised as a welfare issue of importance by A (only 3% reported it as the 1^o cause of poor welfare, $P < 0.001$). Both infectious disease and mastitis were more of a cow welfare concern to F (71.4% and 75% reported them as the 1^o cause of poor welfare, respectively) than to V (19.1% and 18.8%, respectively) or A (9.5% and 6.3%, respectively), ($P < 0.01$).

Conclusions: Vets considered lameness as the main welfare issue for cows and poor BCS and infectious diseases of lesser importance compared to farmers. Advisors considered lameness to be a much lower welfare priority than either vets or farmers. These hazard perception gaps indicate a lack of consensus amongst key stakeholders on the primary welfare issues for cows in expanding pasture-based herds. This has implications for the development of strategies to protect dairy cow welfare and suggests that there is a need for better knowledge dissemination on cow welfare issues across, and better communication on the topic between, stakeholder groups.

Animal Welfare

P02-002-019

Association of floor type on health parameters of cattle fed indoors during the finishing phase

Renee Dewell¹, Grant Dewell², Russ Euken³, Larry Sadler⁴, Chong Wang²

¹CFSPH, ²VDPAM, ³Agriculture and Natural Resources, ⁴Department of Animal Sciences, Iowa State University, Ames, United States

Objectives: The use of indoor confinement concrete slatted floor feeding facilities has grown in the U.S. to comply with increasing environmental regulations and decreasing land availability. Rubber mats manufactured to be installed on top of concrete slats are being promoted to increase comfort and improve welfare and performance. The objective of this project was to evaluate potential health differences associated with various types of slatted flooring in confined beef operations during the finishing phase of production.

Materials and Methods: A cohort study design was conducted using the following groups: Kraiburg slatted flooring mats, Animat rubber flooring, Easy Fix Slat Rubber Solutions for Beef flooring mats, and concrete- only slatted floor pens. For statistical purposes, data was grouped and assessed as mats vs. concrete. Feeder calves were sourced through normal channels by the feedlot's cattle buyer. Calves were individually assessed for general health and existing lameness prior to enrollment. Cattle were evaluated individually and then data were assessed at the pen level. Pen-level morbidity and mortality were assessed. Locomotion scores were assessed at enrollment and within 7 days of slaughter. Descriptive statistics were generated for health and performance outcomes for individual animals and also on a pen basis. ANOVA statistics were used to determine statistical differences

between health and performance parameters between the two groups. Significance was set at 0.05.

Results: Concrete-only pens demonstrated decreased health benefits compared to mat pens. Twelve concrete-only pens and 23 mat pens were included. Compared to cattle on rubber mats, cattle on concrete-only tended to have higher morbidity (17.7% versus 6.6%; $p = 0.07$). When genders were compared within treatment groups, pens of steers on concrete-only pens had higher morbidity (29.7 vs. 10.3%). When gender was examined for mat pens, pens of steers had a 17.8% morbidity rate compared to pens of heifers (5.5%). Pens of cattle on concrete-only slats had 3.1% lameness compared to 1.1% lameness for pens of cattle on mats ($p = 0.02$). When genders were compared between treatment groups, results were very similar (concrete-only: heifers 3.1%, steers 3.2%; mat pens: heifers 1.1%, steers 1.5%). Concrete-only pens also had a higher mortality rate compared to mat pens (1.9% versus 0.7%; $p = 0.03$). Pens of cattle on concrete-only pens had higher locomotion scores compared to pens of cattle on concrete-only (concrete-only 2.1%; mat pens 1.6%).

Conclusions: This study demonstrated increased health benefits for rubber mats. Pens finished on concrete-only slats were more likely to have increased locomotion scores, be identified and pulled for lameness, and have higher mortality. Evaluating the impact of various slatted flooring with health and performance among confined beef cattle in a production setting is important to improve to ensure both the wellbeing of fed cattle and economic viability of cattle feeders. Further work should be done to measure potential differences between mat types as well as economic benefit.

Effects of season of the year on transport-related mortality in fattened cattle

Eva Voslarova¹, Vladimir Vecerek¹, Veronika Simova¹, Iveta Bedanova¹

¹Department of Veterinary Public Health and Animal Welfare, Faculty of Veterinary Hygiene and Ecology, University of Veterinary and Pharmaceutical Sciences Brno, Brno, Czech Republic

Objectives: Adverse climatic conditions are strong stressors that animals can face during transport. Ambient temperature affects trailer internal conditions and inadequate microclimate may be one of the largest threats to animal welfare during transportation. Shortcomings in animal welfare during the transportation of cattle may lead to the increased mortality of animals and impaired quality of meat. The aim of this study was to determine the effect of season of the year on the transport-related mortality rate in fattened cattle transported for slaughter in the Czech Republic in the period from 2009 to 2014.

Materials and Methods: Data summarizing the numbers collected from all transports of fattened cattle for slaughter in the Czech Republic in the monitored period were gathered in the database of the Information Centre of the State Veterinary Administration. Seasonal impact, shown by the four seasons: spring (March, April, May), summer (June, July, August), autumn (September, October, November) and winter (December, January, February), on the mortality of cattle during their transport to the processing plants was determined in such a way that for the individual seasons for the whole monitored period, the total numbers of transported cattle and the total numbers of cattle having died were determined and mortality in percentages were calculated for the period from 2009 to 2014. All the data were analysed using the statistical package Unistat v.

6.5. Statistical comparisons between the frequencies of the categorical variables of interest were performed with the Chi-square test (with Yates correction when needed) within the contingency table procedure. Data concerning transport-related mortality rates were compared between the individual seasons monitored in the period from 2009 to 2014.

Results: In the monitored period, in total 631,596 heads of cattle were transported for slaughter, out of which 111 (0.018%) died as a result of this transportation. It follows from our results that season of the year had an important effect on the transport-related mortality rate in fattened cattle. The highest mortality rate (0.032%) was observed in spring months. This was significantly higher ($P < 0.05$) than mortality rate of cattle transported for slaughter in any other season of the year. Lower death losses were associated with transports carried out in summer months (0.018%) and winter months (0.011%). The transport-related mortality rate did not differ significantly in summer and winter. The lowest mortality rate (0.009%) was found in autumn months. The results suggest that it is not extreme ambient temperatures in summer and winter months but rather another factors that are responsible for variability in death losses in cattle transported for slaughter in different seasons of the year. The possible grounds for the highest mortality rate being found in spring months are as follows: reduced quality of feed material, weakened immunity of animals after winter season, increased occurrence of respiratory infections during spring time.

Conclusions: It is obvious from the results that the season of the year plays an important role in terms of animal welfare during the transportation process. As early in course of the route planning, expected effects of the given season should also be taken into consideration.

P02-002-021

Case-control study on behaviour of calves related to automatic calf feeding systems after cauterly dehorning with an additional meloxicam treatment

Anne Dol¹, Ruben Tolboom²

¹Diergeneeskundig Centrum Zuid-Oost Drenthe, Coevorden,

²Boehringer Ingelheim, Alkmaar, Netherlands

Objectives: In this case-control study the effect of an additional meloxicam treatment on the behaviour of calves following cauterly dehorning with local anaesthetic and systemic sedation was measured with an automatic feeding systems on commercial dairy farms in the Netherlands. This study was initiated and executed by a veterinary practice in the Netherlands.

Materials and Methods: Five commercial dairy farms were enrolled in this case-control study. All these farms were using the Forster automatic system to feed milk replacer to their calves. In total 54 calves were studied, distributed respectively from farm 1 to farm 5; 12 calves, 24 calves, 4 calves, 9 calves and 5 calves. The dehorning procedure of the calves was done by the same veterinarian throughout the whole study. Calves were first sedated with Xylazine (1ml per calf, Sedamun Dechra), a procainehydrochloride corneal nerve block was given (5ml per horn, Procamidol AST). Calves were blocked by age and randomly assigned to receive a subcutaneously injection of meloxicam (NovemBoehringer Ingelheim, 2.5ml per kg body weight, T-group, 28 animals) or no additional treatment (NOT-group, 26 animals). The meloxicam was given shortly after the procainehydrochloride administration. Treatments were given approximately 5-10 minutes before cauterly dehorning. Only healthy calves without other treatments were enrolled. A continuous observation

was performed by the farmer collecting the data from the automatic feeding system from 2 days before until 3 days after the dehorning. The feeding protocol of the calves on these farms was similar, they were fed milk replacer at a schedule provided by Forster and calves had a fixed limited amount of visits where they could gain milk replacer. Therefore the automatic feeding system measures successful visits when the calves are able to drink milk replacer during 24 hours (MV) and the total visits during 24 hours (TV). The group size of the calves was between 6 and 14 per artificial nipple. Behaviour data was analysed using Excel, with the student T test to determine the difference between treatment groups (p-value

Results: The mean age of the NOT-group was 40.8 days with a standard deviation of 15.2; the mean age of the T-group was 48.5 days with a standard deviation of 20.4 days. There was no statistical difference between the groups (p-value=0.11). The mean TV (total visits during 24 hours) of the NOT-group calves during the period before dehorning (from day -2 until -1) was 35.0 with a standard deviation of 22.0. The mean TV of the T-group calves during the period before dehorning was 35.4 with a standard deviation of 25.6. There was no significant difference between these treatment groups (p-value = 0.93) before dehorning. The mean TV of the NOT-group calves during the period after dehorning (from day 0 until 3) was 31.8 with a standard deviation of 20.7. The mean TV of the T-group calves during the period after dehorning was 38.5 with a standard deviation of 24.5. There was a significant difference between these treatment groups (p-value = 0.02) after dehorning. The mean MV (successful visits when the calves were able to drink milk replacer during 24 hours) of the NOT-group during the whole monitoring period (day -1 until 3) was 4.6 with a standard deviation of 2.5. The mean MV of the T-group in this period was 4.4 with a standard deviation of 2.5. There was no statistically difference in the mean MV between the treatment groups (p-value = 0.21) during this period. This result could be due to the fact that the fixed amount of visits where the calves could drink milk where relatively low to the total amount of visits of the calves.

Conclusions: The additional use of meloxicam after cauterly dehorning had behavioural effects which could be measured with an automatic feeding system. The total visits of the calves after dehorning to the automatic feeding system were positively influenced by the meloxicam treatment. This effect could be explained by a prolonged painless period after the cauterly dehorning procedure. A larger study, with for example webcams added in the protocol, could combine the data of the system with the actual behaviour.

Validation of a novel pedometer algorithm as indicator of animal welfare in a dairy Mediterranean buffalo herd

Luigi D'andrea¹, Jacopo Guccione¹, Maher Alsaad², Giuseppe Molinaro¹, Angela De Rosa¹, Adrian Steiner², Paolo Ciaramella¹

¹Department of Veterinary Medicine and Animal Production, University of Studies of Napoli "Federico II", NAPOLI, Italy, ²Clinic for Ruminants, Department of Clinical Veterinary Medicine, Vetsuisse-Faculty, University of Bern, Bern, Switzerland

Objectives: Change of animal behavior is one of the most important criteria for assessing animal welfare and health. Parameters of animal behavior can be used to build up an early disease warning system aiming to gain a higher health standard. Although this concept is well established

in dairy cows, it is far to be implemented in dairy Mediterranean buffalo (MB). Considering these premises, the aim the current study was to validate in dairy MB a novel algorithm to monitor locomotor behavior based on the output of a 3-dimensional accelerometer, recently established for cows.

Materials and Methods: Fifteen healthy primiparous MBs, kept in a free stall, located in Caserta district, South of Italy were enrolled. Data regarding, standing, walking and lying activities were collected by mean of continuous videotaping (HD-Digital System, Conceptronic, Germany; gold standard), and simultaneous recording of locomotion with 3-direction accelerometers, attached to the metatarsus of one hind limb (RumiWatch®, ITIN+HOCH GmbH, Fütterungstechnik, Liestal, Switzerland). Validation of the algorithm was divided into 2 major experiments. Experiment 1 was performed to validate dichotomic (i.e. stand-up, lie-down, number of lying bouts) and continuous output data (i.e. lying time), using a data acquisition period of 24h. Experiment 2 was performed to validate the number of strides. The latters originated from 3 data acquisition periods (video recording and pedometer) of continuous non-lying activity of 20 minutes each one. Data obtained from the gold standard and the pedometers were compared, calculating proportions (dichotomous data) or the mean relative measurement error (RME) (continuous data) according to the following formula: percent deviation = $(100/\text{video-recording observation}) \times \text{absolute value (video-recording observations - pedometer observations)}$. RME <1% was rated very low, 1 to 5% was rated low, and 6 to 20% was rated moderate. Agreement between continuous variables was expressed by means of Spearman nonparametric correlation coefficient (r_s). All statistical analyses were undertaken using SPSS (Version 17.0, SPSS, Chicago, IL).

Results: In experiment 1, all stand-up ($n = 110$) and lie-down events ($n = 110$) and all lying bouts ($n = 113$) were correctly detected, while only 2 out of 224 walking bouts (0.89%) were not recorded by the algorithm. A very low mean RME associated with the estimated lying time (546.29 min/animal, mean value) was detected (0.13%), with a very high correlation compared with the video recordings ($r_s = 1$, $P < 0.0001$). In experiment 2, the median number of strides per 60 min of recording time was 67 (range: 46–116 strides), with a mean RME of 8.61%, and a very high correlation of $r_s = 0.957$ ($P < 0.0001$) between video recordings and algorithm output was estimated.

Conclusions: Health monitoring by means of an automated livestock management system was performed for the first time in MB. The encouraging preliminary results suggest that the novel pedometer may detect several locomotion behaviors in these ruminants with a high accuracy. The differences detected in the walking activity can be related to a specific scratching behavior present in MB but not found in cattle and misclassified by the software. Further investigations are warranted to eliminate this error and validate additional parameters.

Objectives: The purpose of this study was to compare a one-time oral administration of four non-steroidal anti-inflammatory drugs in their ability to control the pain and distress associated with cautery dehorning in dairy calves. The NSAIDs investigated have pharmacokinetic properties in cattle that produce a persistent plasma concentration, which may allow for prolonged analgesia with the added practicality of a simple administration regimen. All drugs were administered orally at the same dose on a mg/kg basis.

Materials and Methods: One hundred and eighty five calves aged approximately 6 to 9 weeks old were either sham dehorned ($n=31$) or cautery dehorned following oral administration of carprofen ($n=31$), firocoxib ($n=31$), flunixin meglumine ($n=30$), meloxicam ($n=31$) or a placebo in randomized, controlled trial. A standard dose of 2.0 mg/kg was given to all calves receiving an oral NSAID. In addition, all calves received local anesthesia prior to actual or sham dehorning. Cortisol concentrations, heart rate, mechanical nociception thresholds, ocular and dehorning area temperatures and average daily gains were evaluated. A linear mixed effects model with repeated measures was used for statistical analysis. Planned contrasts evaluating analgesic treated calves and placebo treated controls were also analyzed.

Results: Analgesic administration was associated with changes in ocular and dehorning area temperature differences ($P=0.020$). In addition, administration of oral meloxicam, flunixin meglumine, and firocoxib resulted in decreased cortisol concentrations compared to placebo treated controls for the first 24 h post-dehorning (AUROC-24) ($P=0.0499$). Moreover, meloxicam attenuated the maximum cortisol released compared to placebo treated calves ($P=0.018$). Although carprofen administration reduced heart rates after 24 h ($P=0.0466$), it was unable to control the acute stress associated with cautery dehorning during the initial 24 h. Although a treatment effect ($P < 0.0001$) was observed in the determination of mechanical nociception threshold among all treatment groups, no differences were observed among treatment groups dehorned. Average daily gain was not affected by treatment ($P=0.91$).

Conclusions: A one-time dose of 2.0 mg/kg of oral meloxicam, flunixin meglumine, or firocoxib reduced the acute stress response associated with cautery dehorning; however, carprofen administration was associated with increased cortisol concentrations and dehorning area temperatures for the initial 24 h. Given the reduction in maximum cortisol concentrations, meloxicam appears to be the most potent NSAID evaluated.

Heart rate and cardiac vagal tone of Holstein–Friesian dairy cows with assisted calvings

Levente Kovács¹·Fruzsina L. Kézér¹·Ferenc Ruff²·Ottó Szenci¹¹MTA-SZIE Large Animal Clinical Research Group, Üllő, ²Department of Methodology, Hungarian Central Statistical Office, Budapest, Hungary

Objectives: Besides several aspects of management, giving assistance in calving has a great importance. Careful assistance can help to minimize unnecessary pain and distress during calving; however, care must also be taken when deciding on the necessity and timing of assistance during calving. In the present work, we were interested in whether the timing and technicality of obstetrical intervention (early and unnecessary vs. professional) and the management of parturition (individual vs. group calving) has an impact on cow welfare during calving in the early postpartum.

Materials and Methods: Heart rate (HR) and the high frequency (HF) parameter of heart rate variability were calculated, the latter is highly sensitive for alterations in cardiac vagal tone. We divided calvings into four groups as follows: 1) unassisted calving in the individual pen (UCI, n = 21); 2) unassisted calving in the group pen (UCG, n = 19); 3) assisted calving with professional obstetric intervention (ACP, n = 20); 4) assisted calving with inefficient obstetric intervention (ACIN, n = 19). HRV analysis was performed for the following periods of the peripartum: 1) prepartum period (PREPART) between 96 h before the onset calving restlessness and; 2) parturition (PART) (between calving restlessness and the time of birth); and 3) postpartum period (POSTPART) between birth and 48 h after calving. HR and HF parameters were calculated as areas under the curves (AUC). Behavior was recorded with a closed-circuit camera system including two day/night outdoor cameras installed above the pen allowing subsequent matching of the stages of calving and HR recordings.

Results: No difference was found between calving groups in areas under the HR and HF curves during PREPART. Heart rate AUC_{PART} was similar across UCG and ACP groups (P = 0.875), but it was greater in these groups than in UCI cows (P = 0.008 and P = 0.033, respectively). Heart rate AUC_{PART} was greater in ACIN animals compared to any other calving groups (P < 0.001 for all comparisons). AUC_{POST} differed not across UCI, UCG and ACP groups (P = 1.000 for all comparisons), but it was greater in UCIN cows than in animals from UCI, UCG and ACP groups (P = 0.022, P = 0.001 and P = 0.014, respectively). HF AUC_{PART} was similar across UCG and ACP groups (P = 0.386), and across UCI and ACP (P = 0.299) as well, however, it was greater in UCG cows compared to UCI cows (P = 0.011) reflecting on higher parasympathetic tone of animals calved in group. HF AUC_{PART} was lower in ACIN cows compared to the other calving groups. Area under the HF_{POST} curve was similar across UCI, UCG and ACP groups (P = 1.000 for all comparison), but it was lower in UCIN cows than in animals from UCI, UCG and ACP groups (P = 0.006, P = 0.005 and P = 0.001, respectively). Cows from UCI, UCG and ACP groups showed a similar parasympathetic activity within POSTPART (P = 1.000 for all comparison), while vagal tone had the lowest peak in ACIN cows as reflected by HF minimum (P < 0.001 in all comparisons). Similar to HR, HF required shorter time to return baseline levels in UCI, ACP and ACIN groups than in UCG cows (P < 0.001 for all comparisons) and time to return to baseline was similar between the former groups.

Conclusions: Heart rate and cardiac parasympathetic activity reflects on a higher stress load on ACIN cows compared to the other groups during parturition and in the early postpartum. Our data demonstrate the impact of appropriate timing and technicality of obstetrical intervention on cattle welfare in cases of assisted calvings. Based on the present

findings, physiological indicators of stress, such as HRV particularly during the peripartal period may reveal opportunities for improvements in calving management in the future.

Animal Welfare

P02-002-025

Cortisol concentrations, heart rate and heart rate variability of dairy cows with different temperament during and after transrectal examination

Fruzsina Luca Kézér^{1,2}·Levente Kovács²·Margit Kulcsár-Huszenicza³·Ferenc Ruff⁴·Ottó Szenci²¹Institute of Animal Husbandry, Faculty of Agricultural and Environmental Science, Szent István University, Gödöllő, Gödöllő, ²MTA-SZIE Large Animal Clinical Research Group, Üllő, ³Department and Clinics of Reproduction, Faculty of Veterinary Science, ⁴Department of Methodology, Hungarian Central Statistical Office, Budapest, Hungary

Objectives: Hypothalamic–pituitary–adrenal (HPA) axis and cardiac autonomic nervous system (ANS) activity was evaluated in response to transrectal examination in non-lactating Holstein–Friesian cows with different temperament. The main objective of our study was to determinate the differences in pain-related behaviors, plasma and salivary cortisol concentrations, heart rate (HR) and heart rate variability (HRV) related to behavioral characters before, during and following transrectal examination.

Materials and Methods: Frequency of behaviors (restlessness, step/kick behavior and urination/defecation/vocalization) performed during fixing the heart rate monitors were used to classify cow temperament as Low Responder [consisted of 20 cows with the lowest reactivity (n = 20)] or High Responder [the 20 cows with the highest reactivity (n = 20) to the procedure]. The measurement period lasted from the last 5 min before the examination until 120 min after the procedure has finished. Activity of the autonomic nervous system was assessed by HR and HRV parameters. Blood and saliva samples were collected at 5 min before (baseline) and 0, 5, 10, 15, 20, 30, 40, 60 and 120 min after the examination has finished to determine cortisol concentrations. Cardiac parameters included HR, the root mean square of successive differences (RMSSD) between the consecutive interbeat-intervals, the high frequency (HF) component of HRV and the ratio between the low frequency (LF) and HF parameter (LF/HF ratio).

Results: Baseline levels of plasma and saliva cortisol did not differ between groups. Following the examination, peak plasma and saliva cortisol levels (P = 0.002 and P = 0.001, respectively) and the amplitude of the plasma and saliva cortisol response (P = 0.001 and P = 0.003, respectively) were higher in High Responder cows than in Low Responders. Areas under the plasma (P = 0.020) and saliva cortisol response curves (P = 0.037) were greater in High Responder cows. Plasma and salivary cortisol levels correlated significantly at baseline (r = 0.91, n = 40, P = 0.001), right after examination (r = 0.98, n = 40, P = 0.001) and at peak levels (r = 0.96, n = 40, P = 0.001). Basal heart rate was higher in High Responder cows than in Low Responder cows (P = 0.017). Area under the heart rate response curve was higher in Low Responder cows than in High Responders (P = 0.033), however, maximum heart rate and the amplitude of the heart rate response showed no differences between groups. Baseline values of RMSSD and HF did not differ between groups. Minimum values of both parameters calculated for the 5-min transrectal examination were

higher in High Responder cows. Following the examination, response parameters of RMSSD and HF did not differ between groups. Except from baseline values, the maximum ($P = 0.004$) and the amplitude of LF/HF ratio response ($P = 0.001$) and area under the LF/HF response curve ($P = 0.022$) were lower in Low Responder cows compared to High Responders suggesting lower sympathetic activation of the ANS in Low Responder animals.

Conclusions: Our results demonstrate that cortisol concentrations and parameters of HRV may complement each other, providing a reliable option for the assessment of acute pain in dairy cattle. Animals with an excitable temperament exhibit increased plasma and salivary cortisol concentrations and higher cardiac autonomic responsiveness to transrectal examination than calmer cows. Salivary cortisol could substitute for plasma cortisol when assessing response of cattle to severe stress.

Animal Welfare

Welfare parameters in dairy cows reared in tie-stall and open-stall farming systems

Maria Novella Benvenuti¹ Lorella Giuliotti¹ Claudia Lotti² Pier Attilio Accorsi³ Petrulli C. Adele³ Andrea Martini^{4,*}

¹Scienze Veterinarie, Università di Pisa, Pisa, ²Scienze delle Produzioni Agroalimentari e dell'Ambiente, Università di Firenze, Firenze, ³Scienze Mediche Veterinarie, Università di Bologna, Bologna, ⁴Scienze Produzioni Agroalimentari e dell'Ambiente, Università di Firenze, Firenze, Italy

Objectives: Housing and management conditions are expected to affect dairy cattle welfare. The animals could experience pain or distress as a result of widely accepted management practices, and possibly suffer being kept under apparently "unnatural" conditions. The animal welfare assessment requires the use of multiple indicators in order to analyse the heterogeneity of aspects involved. The aim of this study was to compare animal welfare of dairy cows reared in tie-stall and open-stall system by means of metabolic, immunological and stress related parameters.

Materials and Methods: The study involved 80 pluriparous lactating cows belonging eight dairy farms located in the area of Mugello (Florence district) reared in different system: tie-stall (TS) and open-stall (OS). Ten blood samples were collected in the morning from the jugular vein using vacutainer tubes containing EDTA to estimate non esterified fatty acids (NEFA), total proteins (TP), creatinine (Creat), nitrogen ureic (BUN), betahidroxiacetato (BHBA), aspartate-aminotransferase (AST) alanina-aminotransferase (ALT), calcium (Ca), chloride (Cl), potassium (K), oxygen free radicals (OFR), haptoglobin (HP), serum lisozyme (SL), bactericidal activity (SBA) and hair cortisol. Hair samples were carefully cut from the tail switch using clippers and were frozen at the temperature of -20°C ; cortisol was analysed by the method described by Accorsi et al. At the same time body condition score (BCS) was recorded. The experiment was performed in accordance with European Commission regulations (86/609/EEC) and Italian law (116/92).

Results: Results showed that the housing system affected some parameters such as ALT, AST, N ureic, BHBA, OFR and cortisol. Most of these showed mean values within the range of reference without revealing signs of suffering. An interesting outcome regarded OFR level that resulted higher in the OS system likely as consequence of a higher productive effort. Results regarding hair cortisol were particularly interesting because it is known as an indicator of chronic stress: TS

displayed significant ($P < 0.001$) higher mean value than OS (2.8 ± 1.43 vs 1.6 ± 1.05 pg/mg respectively). The two housing systems did not differ for BCS, that was 3.1 and 3.0 respectively for both the solution.

Conclusions: In this study did not emerge a situation of evident suffering in animals reared in TS. Tethered cows may have an improved welfare quality if they benefit from comfortable and clean stalls, quantitatively and qualitatively adequate feeding and watering, access to exercise and not in the least a good relationship with the stockperson.

Higher animal welfare systems: The business case for beef cattle

Ines Ajuda^{1,*}

¹Food Business programme - CIWF, Godalming, United Kingdom

Objectives: Food businesses struggle to find higher animal welfare standards that are applicable to different parts of the globe. Even when working in countries with a good animal welfare (AW) assurance schemes' penetration, it is very challenging to find AW assured beef cattle. To overcome this challenge, food companies perform their own audits or questionnaires on the different suppliers. In order to support those companies to find beef suppliers that operate under higher animal welfare conditions, the Food Business Programme at CIWF has produce different resources, being one of them the animal welfare potential matrix.

Materials and Methods: The animal welfare potential matrix is a summary table which outlines the welfare potential by production system using a 'Bad-Better-Best' model, showing a summary version of the different systems that companies can find in their supply chain and can be consider better or best in terms of animal welfare. To define the bad, better and best systems in beef production and to make sure they were globally relevant, commercially viable and sustainable, different experts around the world were consulted, as well as different companies that are already working with higher animal welfare cattle in their supply chains. Also, to make sure the document was science based, a literature review of the main welfare issues in beef cattle was made. The structure of the document followed previous ones from other species, taking into account the three components that generate quality of life to the animals: mental wellbeing, physical wellbeing and expression of natural behaviour. The better model for beef cattle, which is the most commonly used by companies as a reference of a commercially viable higher Animal Welfare system, features a semi-extensive system that is pasture reared during grazing season and higher animal welfare housing when off pasture.

Results: The matrix is now being used by different companies to characterise current suppliers and look for prospect ones; to feed into animal welfare policies and as a support document to create questionnaires for internal and own audits to the suppliers. The first results show a tendency from companies to start to source their beef cattle from countries that are able to produce pasture based beef cattle (even if just for a limited part of the year). One interesting finding related to pasture based systems was that food businesses' interest shown on pasture is not just based on an animal welfare component, but is also based on a holistic approach to sustainability, including economic volatility, environmental impact, low risk investment and as a point of differentiation in parts of the world where the meat consumption has reached a plateau and will probably decrease. Finally, it was reported by

different companies that there are still major difficulties to find suppliers housing beef cattle housed in higher animal welfare conditions, mainly due to the fact that this side of the production is not as valued and recognised as the pasture use.

Conclusions: The beef welfare potential matrix features better and best models of animal welfare that are commercially viable at a global level. It has shown that there is a business case for beef sourced from higher animal welfare systems that include pasture based systems as well as higher animal welfare housing.

Thermographic images for heat tolerance evaluation in Curraleiro Pe-Duro, Pantaneiro and Nelore cattle

Caio C. Cardoso ¹Flávia G. de Lima ²Maria Clorinda S. Fioravanti ²Andrea A. do Egito ³Vanessa Peripolli ¹Candice B. Tanure ¹Tiago D. P. Paim ¹Concepta McManus ¹

¹University of Brasília, Brasília, ²Veterinary and Animal Science School, Federal University of Goiás, Goiânia, ³Embrapa Beef Cattle, Campo Grande, Brazil

Objectives: Adaptability evaluation and heat tolerance of the animals are mainly determined by the physiological parameters such as respiratory rate and body temperature. However, new tools, such as infrared thermography, are alternatives to assess the impact of environmental factors on thermal stress in animals. Therefore, the objective of this study was to compare physiological and thermographic responses to heat stress in three breeds of cattle.

Materials and Methods: Forty-five males of the Pantaneiro, Curraleiro Pe-duro and Nelore breeds (15 animals each), approximately three years of age were used. The animals were reared as one group with the same environmental and treatment conditions and were fed with a 70% roughage and 30% concentrate diet on a dry matter basis. For the duration of the experiment, animals were maintained in a roofless corral with lateral wooden slating. Before physiological collections, the animals were maintained in an open corral for at least two hours without shade and contained in a chute. The physiological parameters measured included: respiratory rate, heart rate and rectal temperature, evaluated during the morning at 8:30h, and in the afternoon, at 15:30h, with six repetitions. Animal surface and ground temperatures were obtained using an infrared camera FLIR® T400. Two images were taken from each animal, at a distance of 1.5m, one laterally of the whole body and the other of the head region. For this, the animals were taken calmly to a covered area immediately after physiological measurements, so no time was allowed for the animals to adapt to the shaded area before recordings were completed. Standard Quickreport® tools were used for analysis of the images. Air temperature, wind speed, relative humidity were obtained from a mobile weather station and used to calculate the temperature and humidity index (THI). The statistics analysis included an analyses of variance, correlation, principal factors, as well as canonical analyses.

Results: Breed affected all physiological parameters and all surface temperatures ($P < 0.05$). Nelore breed had the lowest heart rate (103.91 mov/min). The Curraleiro Pe-duro breed had the lowest body area (35.34°C), neck (35.36°C), rump (35.14°C), head (35.38°C), groin (34.79°C) and axilla (35.14°C) temperatures as well as rectal temperature (38.63°C) and the highest respiratory rate (46.55 breaths/min). The period of the day influenced the surface temperatures, as well

as respiratory and heart rate of the animals ($P < 0.05$). In the morning period, the Curraleiro Pe-Duro breed showed the lowest values of body area (32.87°C), neck (33.22°C), rump (31.77°C), muzzle (29.07°C), head (31.64°C), groin (32.22°C) and axilla (32.74°C) temperatures, compared to the other breeds. In the afternoon period, little difference in the surface temperatures was observed among the breeds studied. For the physiological parameters, the Nelore breed showed the lowest heart rate, both in the morning and in the afternoon, as well as the higher rectal temperature and the lowest respiration rate, in the afternoon period. For the Curraleiro Pe-Duro breed, the respiratory rate was higher, especially in the afternoon. The correlations between the surface and the environment temperatures were high and positive. Rectal temperature showed a low correlation with respiratory rate (0.21) but was not correlated with heart rate (0.05). The principal component analysis showed that 76% of the variation was explained by the surface temperature, physiological and environmental parameters evaluated.

Conclusions: The Curraleiro Pe-Duro breed had the lowest rectal and surface temperatures independent of the period evaluated, with fewer animals that suffered with the climatic conditions, so this may be considered the best adapted when heat challenged under the experimental conditions. Thermography data showed a good correlation with the physiological indexes, and body area, neck and rump were the main points.

Heat stress response in zebu cattle using physiological traits and thermographic images

Caio C. Cardoso ¹Vanessa Peripolli ¹Carlos F. Martins ²Álvaro M. da Fonseca Neto ²João Batista G. Costa Jr. ¹Concepta McManus ¹

¹University of Brasília, ²Embrapa Cerrados, Brasília, Brazil

Objectives: As heat stress can affect the productive and reproductive life of beef cattle, this study was carried out to evaluate the heat tolerance of five zebu cattle breeds using physical, physiological and hematological traits as well as thermographic responses.

Materials and Methods: Forty cows of the Gir, Girolando, Nelore, Sindhi and Indubrasil breeds (eight cows each), approximately three years of age, non-pregnant and non-lactating were evaluated. Body weight, withers and hump heights as well as thoracic circumference were recorded using a measuring tape. The density and length of the hair as well as skin color and thickness were evaluated. The physiological parameters measured included: respiratory rate, heart rate and rectal temperature, evaluated during the morning and in the afternoon. Blood samples were collected for hematological evaluation. Animal surface and ground temperatures were obtained using an infrared camera FLIR® T400. Two images were taken from each animal, at a distance of 1.5m, one laterally of the whole body and the other of the head region. Standard Quickreport® tools were used for analysis of the images. Red and white cell number, platelets and hemoglobin concentration were obtained using an automatic cells counter. Monocytes, lymphocytes, segmented neutrophils and eosinophils numbers were obtained by counting one hundred cells under a microscope. Total plasma protein concentration was determined by refractometer. Air temperature, wind speed, relative humidity were obtained from a mobile weather station and used to calculate the temperature and humidity index (THI). The statistics analysis included an analyses of variance, principal factors, as well as logistic regression and calculation of odds ratio.

Results: Breed influenced all the physical traits ($P<0.05$). Indubrasil and Girolando animals had the highest body weight and thoracic circumference (559.75 and 552.12 kg and 2.05 and 2.05 cm, respectively) however, Girolando and Nelore animals had highest withers height (1.40 and 1.39m, respectively). There were significant differences in the rectal temperature, heart and respiratory rates between breeds ($P<0.05$). Gir and Indubrasil breeds had the highest rectal temperatures (39.05 and 39.00°C, respectively). Breed was significant for surface temperatures ($P<0.05$). Eye and brain surface temperatures were the most affected by environmental parameters. Also, environmental parameters affected packed cell volume and red cell number. Nelore animals had the lowest packed cell volume (37.46) and Nelore and Indubrasil animals had the lowest value of total plasma protein (7.58 and 7.46, respectively). The principal component analysis showed that in the morning, 63.13% of the variation was explained by the physiological and physical variables of the animals. Odds ratio test showed that the Gir breed was three times more likely to have higher rectal temperature compared with Sindhi as confirmed by the logistic regression. When the black globe temperature approached 35°C, the probability of the Gir animals having rectal temperatures above normal was approximately 70%.

Conclusions: Physical characteristics were important in assessing the physiological response when animals were heat challenged, but these characteristics alone are not responsible for conferring tolerance to heat, which also included a set of morphological characteristics and physiological adjustments. Gir animals were the least adapted to the climatic conditions of the experiment and Girolando and Sindhi breeds showed the best physiological indices when heat challenged. Thermography showed a high correlation with the physiological indexes, especially with the rectal temperature and surface temperatures and axilla, neck and eye were the main points.

Effect of space allowance and floor type on intake, performance, hoof condition and blood physiological variables of finishing beef heifers

Michael Keane^{1,2} Mark McGee³ Edward O'Riordan³ Alan Kelly² Bernadette Earley¹

¹Animal and Bioscience Research Department, AGRIC, Teagasc, Grange, Dunsany, Co Meath, ²College of Agriculture, Food Science and Veterinary Medicine, University College Dublin, Dublin 4, ³Livestock Systems Research Department, AGRIC, Teagasc, Grange, Dunsany, Co Meath, Ireland

Objectives: Previous studies have shown that increasing space allowance above 2.0m² for heifers (Fisher et al., 1997) and 3.0m² for steers (Hickey et al., 2003) has no benefit on animal health or welfare. There have been suggestions from advocacy groups in the EU to increase the space allowance for finishing cattle above 3m² per animal although there is no scientific evidence to support this change. Therefore, the objective of this study was to investigate the effect of space allowance (3.0, 4.5 and 6.0 m²) on fully slatted concrete floors and 6.0 m² on straw on intake, performance, hoof health and blood physiological variables of finishing beef heifers.

Materials and Methods: Two-hundred and forty crossbred beef heifers, (mean initial liveweight, 505 (SD 35) kg) were blocked by breed, live weight and age and, from within block, were randomly assigned to one of four treatments; 3.0, 4.5 and 6.0 m² on slatted concrete floors and 6.0 m²

on straw. For each treatment there were six pens of ten animals. They were offered a maize silage and rolled barley based total mixed ration to appetite. Feed was weighed in daily and refusals were measured twice weekly. Heifers were weighed before assignment to treatment (day (d) 0) and at 21 d intervals until slaughter (d 105). Hooves were inspected for lesions on d 0 and d 105. Jugular blood samples (K₃EDTA (1×6 ml) and no-anticoagulant (1× 8.5ml)) were collected at 21 d intervals. Whole blood samples (K₃EDTA) were analysed for haematological profiles (white blood cell, red blood cell numbers and haemoglobin concentrations) using an ADVIA haematology analyser. Serum samples were assayed for metabolite concentrations (total protein, albumin, globulin, non-esterified fatty acids, creatine kinase and beta-hydroxybutyrate) using an Olympus Instrument. Post-slaughter, carcass weight, kill-out proportion, hide weight and carcass conformation and fat score (1-15) was determined. Statistical analysis was done using SAS (version 9.3; SAS Institute, Inc.). The model included the fixed effect of treatment and batch and the random effect of block. Pen was the experimental unit for intake and FCR and animal was the experimental unit for all remaining variables. Haematological data was analysed using repeated measures ANOVA.

Results: There was no effect ($P>0.10$) of space allowance or floor type on DMI. Space allowance had no effect on ADG or FCR ($P>0.10$); however ADG was higher (1.34 v. 1.19 kg) and FCR was better (8.42 v. 9.45 kg) for heifers on straw compared to those on slats at 6.0m² ($P<0.01$). There was no difference in slaughter weight, carcass weight, kill-out proportion, hide weight and carcass conformation score or fat score among treatments ($P>0.10$). Space allowance and floor type had no effect ($P>0.10$) on the number of hoof lesions, blood metabolite concentrations or any of the haematological variables.

Conclusions: Results showed that increasing space allowance above 3.0m² for finishing beef heifers on fully slatted concrete floors did not affect animal intake and performance. At the same space allowance (6.0m²), housing heifers on straw as opposed to concrete slats increased ADG but this did not result in a significantly heavier slaughter or carcass weight. Space allowance and floor type had no effect on hoof health or blood physiological variables.

White Blood Cell Count After Disbudding in Calves Treated with Low Level Laser Therapy

Edlen A. Medeiros¹ Bruna S. Barbosa² Carolina dos Anjos² Fábio P. Sellera² Ronaldo G. Gargano² Lilian R. M. Sá³ Luciana A. Lopes⁴ Fernando J. Benesi² Rogério B. Santos¹ Fabio C. Pogliani^{2,*}

¹Paulista University, ²Internal Medicine, ³Animal Pathology, University of São Paulo, São Paulo, ⁴Nupen – Research and Education Center of Photo Therapy in Health Sciences, São Carlos, Brazil

Objectives: We aimed to investigate the effect of different low level laser therapies (LLL), i.e, red laser and infrared laser, commonly known as cold laser, in the white blood cell count (WBCC) of disbudded calves, as a novel and alternative treatments for wound healing, improving animal welfare by lowering recovery time and decreasing inflammation process.

Materials and Methods: Twelve male Holstein calves, four weeks old, disbudded by hot iron were used in the study. Local anesthesia was performed with lidocaine hydrochloride 2%. The cornual branch of the zygomaticotemporal nerve was blocked associated with infiltrative anesthesia around the cornual button. After hair clipping and antiseptic

with 2% chlorhexidine, bilateral cauterization of germinal buds was made. For pain relief after disbudding, we administered metamizol sodic (25mg/kg, SID) during three days.

The animals were divided into three different treatment groups:

- 1) control (ointment with zinc oxide) - 4 calves;
- 2) LLLT with red laser ($\lambda = 660 \text{ nm}$, 100mW, 2J per point) - 4 calves;
- 3) LLLT with infrared laser ($\lambda = 808 \text{ nm}$, 100mW, 2 J per point) - 4 calves.

Only one treatment with zinc oxide ointment, red laser and infrared laser was made, according to the described groups, immediately after hot iron disbudding.

Blood samples were collected for WBCC evaluation in seven different times: 1h before disbudding; 2h and 4h after disbudding; 3, 7, 14 and 21 days after disbudding.

Statistical analysis was made with Tukey's test ($p < 0.05$) using Minitab Statistical Software.

Results: We compared the total leukocyte count among the different treatments within the same time. According to our results, regardless of the group, statistical analysis showed no significant difference in any of the studied periods. There was no significant difference among the treatments in the total number of neutrophils, eosinophils, basophils, lymphocytes and monocytes within the same time. When the comparisons were made among the different times but within the same group, there was no difference as well.

Local burn injuries could lead to systemic alterations in WBCC if secondary infections and/or severe inflammation were present, but, in our study, there were no animals with systemic responses to them. Therefore, no alterations in WBCC were found regardless to the treatment group.

Conclusions: We concluded that there was no difference in the WBCC in hot-iron disbudded calves, regardless the treatment group. Therefore, the WBCC did not present itself as an accurate indicator for acute inflammation in disbudded calves when local burn injuries remain without complications.

The advantages of LLLT as a practical and effective treatment for wound healing after hot-iron disbudding in calves need to be addressed with more studies concerning novelties for an old practice, improving the animal welfare after such procedure.

Validation of the algometer for measuring udder discomfort in postpartum lactating dairy cows

Catarina Krug¹, Trevor J. Devries^{2,3}, Jean-Philippe Roy^{3,4}, Jocelyn Dubuc⁴, Simon Dufour^{1,3}

¹Département de pathologie et microbiologie, Faculté de médecine vétérinaire, Université de Montréal, St-Hyacinthe, ²Department of animal biosciences, University of Guelph, Guelph, ³Canadian Bovine Mastitis and Milk Quality Research Network, ⁴Département de sciences cliniques, Faculté de médecine vétérinaire, Université de Montréal, St-Hyacinthe, Canada

Objectives: With modern milk production, we may hypothesize that high-producing cows possibly experience some level of discomfort due to udder distension. The pressure algometer has been used to evaluate pain but it was never validated. A pressure (in kg of force, kgf) is exerted

using the device in the body region of interest until the animal responds with an avoidance reaction. Objectives of the current study were (1) to quantify the precision of the measurement when collected multiple times (within and between observer repeatability), and (2) to evaluate whether such a measure would actually represent a valid measure of udder discomfort.

Materials and Methods: 1) Repeatability: algometer measurements were obtained from three herds. In herds A (n=30) and B (n=14) measurements were obtained once a week just before milking during the first two weeks of lactation. In herd C (n=36), measurements were obtained prior to milking, during five consecutive days. Measurements were obtained twice by two operators. The concordance correlation coefficient (CCC) and the limits of agreement plot were used to investigate within and between observer repeatability.

2) Validity: two experiments were conducted. In experiment 1 (herds A and B) cows were randomly selected to be milked incompletely (10-14l of milk/day; n=21) during the first five days in milk or to be milked completely (n=19). Algometer measurements were collected once on each cow during the treatment period. The pressure needed to trigger an avoidance response was then used as outcome variable in a linear regression model with treatment group as the main predictor, and with herd as fixed effect. The hypothesis was that incompletely milked cows would respond more readily to pressure. In experiment 2 (herd C, n=36) measures were collected five times a day during five days: immediately after morning milking (MM; time 0), +4h, +5h30, +7h30 and +8h30 following morning milking. Measurement obtained was used as outcome variable in a linear mixed regression model with time since MM as main predictor, and with day of measurement and cow as random effects. The hypothesis was that cows would respond more readily to pressure with increasing udder filling. A null model was evaluated for variance partitioning.

Results: Algometer measurements were quite repeatable with good within observer agreement (CCC = 0.66; 95% CI [0.57, 0.74]) and moderate between observers agreement (CCC = 0.52; 95% CI [0.38, 0.63]). In experiment 1, mean avoidance response of 6.4 kgf and 5.3 kgf was observed in cows incompletely and completely milked, respectively. Treatment group was not a significant predictor of the cow response to pressure (P=0.22). These results indicate that either the incomplete milking did not cause measurable levels of udder discomfort, or the algometer was not a good device to measure the discomfort. In experiment 2, variation in the algometer response was mostly due to time of the day (51%) and to the cow (40%), while only a small variation was due to the day of the measurement (8%). Response to pressure varied significantly with number of hours after milking (P<0.01); further, parity of the cow significantly affected that relationship. Amount of pressure needed to trigger a response, however, did not decrease with increasing udder repletion (i.e. with no. of hours since milking). Again results may either indicate that udder repletion does not cause discomfort or that algometer is not a good device to measure discomfort associated with udder distension.

Conclusions: This was the first study reporting repeatability of the pressure algometer for measuring udder discomfort and it showed good repeatability. We could not confirm that the algometer provide a valid measure of udder discomfort. Cows' response to the pressure algometer was highly influenced by time of the day at which the measurement was taken and by cows' characteristics.

Effects of Transdermal Flunixin Meglumine on Pain Biomarkers at Dehorning

Michael D. Kleinhenz¹, Nicholas K. Van Engen¹, Patrick J. Gorden¹, Johann F. Coetzee^{1,2}

¹Veterinary Diagnostic and Production Animal Medicine,
²Pharmacology Analytical Support Team (PhAST), Iowa State University, Ames, United States

Objectives: The objective of this study was to evaluate the analgesic effects of topical flunixin meglumine (Finadyne Transdermal; MDS Animal Health, UK) when given at the time of dehorning on pain associated biomarkers.

Materials and Methods: Twenty four weaned male Holstein calves, ages 6 to 8 weeks of age were enrolled into the study. The calves were randomly assigned to one of three treatment groups of: 1) topical flunixin and dehorn (DH-FLU); 2) topical flunixin and sham dehorn (SHAM-FLU); and 3) placebo and dehorn (DH-PLBO). Treated calves had topical flunixin meglumine applied at the label dose of 3.33 mg/kg concurrently with dehorning. Untreated calves had a placebo which matched the drug's color, odor, and viscosity applied at the time of dehorning. The volume of placebo applied was equal to the calculated dose of the drug in milliliters. The dehorning procedure consisted of applying an electrocautery dehorner to the horn tissue for 10 seconds. A second identical dehorner that was not heated was used for the sham dehorning. The sham procedure consisted of applying the dehorner to the horn for 10 seconds. Biomarker parameters collected and analyzed included: infrared thermography (IRT), mechanical nociception threshold (MNT), plasma cortisol, and Substance P. Infrared thermography images for maximum temperature were analyzed using commercially available research software. Plasma cortisol and Substance P concentrations were determined by radioimmunoassay.

Results: There were no differences in the maximum temperatures (°C) detected for the IRT measurements of the medial canthus of the eye, dehorning site and adjacent skin for the DH groups. Mean control point MNT measurements at 49 hours were 3.14 kgF, 3.46 kgF and 1.43 kgF for the DH-FLU, Sham-FLU and DH-PLBO groups respectively (P = 0.0001). No other differences of MNT were detected between groups for the other test sites and time points.

Peak plasma cortisol concentrations were reached at 20 minutes post dehorning for the DH-FLU and DH-PLBO groups and 10 minutes for SHAM-FLU group. Peak plasma cortisol concentrations were 32.0 ng/ml, 12.7 ng/ml, and 28.8 ng/ml for the DH-FLU, SHAM-FLU and DH-PLBO groups respectively. Cortisol concentrations were statistically lower for the DH-FLU group at 90 minutes post dehorning compared to the SHAM-FLU and DH-FLU group (P = 0.04). At 4 hours post dehorning, the concentrations were 6.36 ng/ml, 11.91 ng/ml, and 8.94 ng/ml (P = 0.1142) for the DH-FLU, SHAM-FLU, and DH-PLBO groups.

Substance P concentrations at 2 hours post dehorning were 27.16 pg/ml, 26.04 pg/ml, and 33.09 pg/ml for the DH-FLU, SHAM-FLU, and DH-PLBO groups respectively (P = 0.4577). Substance P concentrations were 27.81 pg/ml, 27.08 pg/ml, and 30.36 pg/ml for the DH-FLU, SHAM-FLU, and DH-PLBO groups respectively (P = 0.8496) at 4 hours post dehorning. No differences in Substance P concentrations between groups were detected for all time points.

Conclusions: Based on the findings presented here flunixin meglumine, when given as a topical solution, does not have significant effects on biomarkers associated with pain. Other NSAIDs, like meloxicam, have been tested to be efficacious at the time of dehorning and may be more appropriate for use.

Education of the Dairy Employee on Animal Care – A Practical Approach using Dairy CARE 365

Michael W. Bolton¹, Paula Ospina², Elizabeth A. Cox¹, J. K. Shearer³, Ben Bartlett⁴, Fred J. Muller⁵, Gregory J. Crosley⁶, Scott Nordstrom¹

¹Merck Animal Health, Desoto, ²Veterinary Extension Associate, QMPS, Ithaca, ³Iowa State University, Ames, ⁴Michigan State University, East Lansing, ⁵Cattle Strategies, PLLC, Sunnyside, ⁶Countryside Vet Clinic, Somerset, Michigan, United States

Objectives: The dramatic increase in the size of US dairy operations in the last two decades changed the dairy employee constituent from family based and local hires to many employees from other countries with a language barrier and no farm animal experience. The goal of Dairy CARE 365 is to illustrate to the consumer that the dairy community is concerned with the welfare of the animals entrusted to their care. The focus of the program has been to educate employees in the area of cattle care and handling, as they are in daily contact with the animals. This education may have a positive impact on both the welfare of the employee and the dairy cow.

Materials and Methods: There are two types of materials that constitute the educational content of the Dairy CARE 365 program. Firstly, and the core of the program, are the training Modules containing self-advancing slides with embedded videos to illustrate proper techniques and procedures. Approximately twenty minutes in length, they are narrated in English and Spanish, with an assessment at the conclusion, also narrated, with a traveling arrow over each response, if lack of literacy is an issue. With successful completion, a certificate is generated for the employee. At present there are seven modules available with topics including low stress cattle handling, euthanasia, treatment of the non-ambulatory cow, and care of the new born calf. The modules were developed through a collaborative effort utilizing several veterinarians with expertise and training in the topic area covered. The second set of materials consists of SOP's (Standard Operation Procedures) in WORD format, with boiler plate language, that is designed to be customized to their specific farm. Through these materials, it is possible to implement this program at a group meeting, and then owners and employees can return to their farm and devise their individual SOP's and utilize the Modules to train employees in these specific areas. The workshops usually consume three hours and we discuss two important SOP's, construct an Animal Care Commitment for each farm, and show a training Module to conclude.

Results: This effort has been embraced by the both the veterinary profession and the dairy community. It has been a great vehicle for veterinarians to facilitate training and aid in SOP development, inserting their expertise into the center of animal care on the dairies they serve. Many of the US milk processing plants are asking their patrons, the farms selling them milk, to attend these workshops. NMPF (National Milk Producers Federation) has partnered with Dairy CARE to utilize these training materials to augment the FARM (Farmers Assuring Responsible Management) program. To date we have distributed, from direct requests, more than 2,500 copies of the Modules, 780 registrants for modules from our website, and they are in 30 countries and translated into 6 different languages. More than 50 Dairy CARE training sessions have been held in 21 States in US, as well as Canada, at the behest of 15 processors (representing more than half of the US dairy herd) and several veterinary clinics. There have been over 1,000 attendees at these workshops representing more than 2 million dairy cows and over 10,000 dairy employees. Finally, other allied industries, such as nutrition

and breeding companies, have utilized these materials to better serve their dairy clients

Conclusions: Everyone involved in the dairy community has the responsibility to aid in the improvement of both the quality of the employee's work environment as well as the welfare of the dairy animal. Dairy CARE 365 addresses both of these needs, and we have had many testimonials regarding increased worker retention, decreased worker and cattle injuries. Certainly the penetration of this program, if nothing more, illustrates the thirst that the dairy community has for employee education. Further research is needed in areas of improving delivery of adult education materials, retention of knowledge, and survey methodology to assess their impact.

Animal Welfare

P02-002-035

An Analysis Of The Drivers Of Nsaid Use Amongst Dairy Farmers And Dairy Veterinarians

Mark Bryan ¹; Shen-Yan Hea ²

¹Head of R&D, ²Epidemiologist, VetSouth Ltd, Southland, New Zealand

Objectives: Non steroidal anti inflammatory drugs (NSAIDs) have well recognised positive effects on animal welfare through the reduction of pain and inflammation, yet the level of NSAID use across farmers is highly variable. Up to a 15 fold difference in the level of NSAID use between low and high users has been documented. The greatest use of NSAIDs is probably in the dairy industry, yet even here, the drivers for dairy farmers' use of NSAIDs in farm animals are not well understood. This study was designed to explore and quantify these drivers.

Materials and Methods: NSAID sales data was collected from the clinic sales database. The volume of NSAID sales was converted into animal daily doses (ADD) to account for the differences in the duration of effect between short acting and long acting NSAIDs, and was standardised by dividing the ADD value by herd size. Farmers were then ranked into three groups based on the level of NSAID use. Furthermore, clients were ranked according to the level of engagement they have with their veterinarian (A, B and C)

An online survey (SurveyMonkey) was set up to investigate potential factors that may influence farmers' use of NSAIDs in animals. The questionnaire was structured to understand a farmer's own perception of pain, their animals', the farmer's understanding of the benefits of NSAIDs, and their demographic information on the likelihood of NSAID use. In addition, a survey for veterinarians was created using an identical format and questions. Furthermore, the veterinarian survey contained several veterinary targeted questions.

Proportions were calculated from categorical data and qualitative data were converted into a numerical scale for the calculation of a mean response score. R was used for data manipulation and analysis.

Results: A total of 49 farmers and 32 veterinarians responded to the survey. High and medium NSAID users tended to have less dairying experience (<11 years) compared with low NSAID users. High NSAID users were more likely to be an "A" client and are engaged with their veterinarian, whereas low NSAID users were more likely to be a "C" client and less engaging with their veterinarian.

Animal welfare was the most important factor that influenced the use of NSAID in animals. The importance of animal welfare increased with the level of NSAID usage.

Veterinary advice and return on investment were also important overall factors, however no trends were observed between the NSAID user groups.

The cost of the product, with holding periods, and non veterinary advice were more important for low NSAID users. A decreasing trend in the importance of these three factors was observed from low users to high users.

Low NSAID users tended to have greater experience in the dairy industry.

In addition to animal welfare, published literature and product potency were important factors for veterinarians. Administration route and free give-aways were not important factors for NSAID use.

There was an increased trend in the level of perceived animal pain from low users to high users and veterinarians. Veterinarians perceived a lower level of pain during caesarean section, gut surgeries and sick cows compared with farmers. In contrast, the level of perceived personal pain (human experience of painful conditions) did not vary between low and high users.

Conclusions: These data are of significant value in identifying the motivations of high and low NSAID users, and understanding some of the barriers to better amelioration of pain and inflammation in dairy cattle. For example, as NSAIDs were only introduced in the last decade or so, older and more experienced farmers may not be as familiar with their use compared with younger clients with more recent education within the dairy industry.

Engagement with veterinarians was highly correlated with use, suggesting that education of lower users needs to take account of these factors.

Animal Welfare

P02-002-036

Effect Of Different Combinations Of Local Anaesthetic, Sedative And Non-Steroidal Anti-Inflammatories On Growth Rate Of Dairy Calves After Disbudding

Andrew Bates ¹; Richard Laven ²; Fleur Chapple ¹; Danielle Weeks ¹

¹Vetlife, New Zealand, Temuka, ²Institute of Veterinary, Animal and Biomedical Sciences, Massey University, Palmerston North, New Zealand

Objectives: The aim of this study was to assess the effect of different forms of analgesia at disbudding on subsequent weight gain of dairy calves. Two different non-steroidal anti-inflammatories with different retail cost profiles were used and the study was designed to provide data which could demonstrate to farmers that improving analgesia is associated with better profitability as well as better calf welfare. It was hoped this would lead to an increase in the number of calves receiving analgesia at disbudding.

Materials and Methods: All calves were disbudded by trained personnel, using six disbudding protocols on 271, 3- to 6-week-old Friesian-Jersey calves. Three people disbudded 136 calves without sedation or local analgesia (non-veterinary method), but 31 received 20 mg meloxicam S/C and 75 received 150 mg ketoprofen I/M. Three different people disbudded 135 calves with sedation and local analgesia (veterinary method), and 30 also received 20 mg meloxicam S/C and 75 received 150mg ketoprofen I/M. Calves were weighed 14 and 3 days before disbudding, 15 and 30 days later. Daily weight gain was analysed using mixed models and ANOVA.

Results: From disbudding to Day 15 calves disbudded with the non-veterinary method receiving NSAID grew faster (0.66 kg/day) than calves without NSAID (0.53 kg/day; $p=0.031$), and there was no significant difference in the effect of either NSAID. An interaction between method and NSAID treatment ($p=0.001$) meant that NSAID treatment did not increase growth rate in veterinary-disbudded calves (0.64 vs. 0.65 kg/day, respectively; $p=1.000$).

From Days 16–30 there was no significant effect of NSAID on growth rate, but veterinary-disbudded calves grew faster (0.74kg/day) than calves disbudded with the non-veterinary method (0.66 kg/day; $p=0.018$). This meant that, if NSAID was not used, over the first 30 days calves disbudded with the veterinary method grew faster than calves disbudded with the non-veterinary method ($p=0.039$). However, if NSAID was used at disbudding there was no difference in growth rate between veterinary and non-veterinary-disbudded calves ($p=0.831$).

Conclusions: Three to 6-week-old dairy calves disbudded with the non-veterinary method with no analgesia grew significantly more slowly over the next 15 days than calves disbudded with the non-veterinary method given NSAID and more slowly over the next 30 days than calves disbudded by the veterinary method given xylazine and lignocaine. However addition of NSAID to the latter protocol had no effect on growth rate. This study adds to the evidence that analgesia during disbudding is beneficial for calf productivity as well as calf welfare.

Comments: In New Zealand, disbudding is usually carried out when the horn buds are 5–10 mm long and can be removed with a heated disbudding iron alone. The procedure may be performed without analgesia even though there is clear evidence that the procedure is painful. The cost of analgesics and the perception that there is no economic benefit to their use is often cited as one of the major influencing factors that motivate producers to not use analgesics in painful procedures.

This work was supported by AgriHealth NZ Ltd.

P02-002-037

Welfare of dairy cattle in the smallholder (zero-grazing) production systems in Nairobi and its environs

Josh Aleri¹; Eddy M. Mogo²; Charles M. Mulei²; James M. Nguhiu²

¹Faculty of Veterinary and Agricultural Sciences, University of Melbourne, Werribee, Australia, ²Department of Clinical Studies, Faculty of Veterinary Medicine, College of Agriculture and Veterinary Sciences, University of Nairobi, Nairobi, Kenya

Objectives: About 70% of dairy production in Kenya is from the smallholder production systems. These production systems are negatively impacted by a number of factors including poor nutrition, substandard husbandry and management practices, lack of appropriate farm inputs, diseases and low incomes. These factors influence the welfare of dairy cattle, hence their importance for its evaluation. This study was designed to determine the welfare of dairy cattle, risk factors and their indicators in the smallholder production units in Nairobi and its environs. Furthermore the farmers' and stockmen's perspectives of animal welfare were assessed.

Materials and Methods: These objectives were achieved through a cross-sectional study carried out in 80 smallholder dairy units purposively selected in Nairobi and its environs, in which 306 dairy cows were examined. The welfare of cattle in these dairy units was evaluated through several methods which included: visual observations

for animal- and farm-level factors that indicate poor welfare of cattle; taking measurements of dairy housing unit dimensions such as cubicle, walk-alley, kerb and feeding bunk; and using a structured questionnaire to interview farmers and stockmen on nutritional regimes and other management practices such as removal of slurry, milking techniques, record keeping and disease control. These factors were recorded and later analyzed. Analyses included descriptive statistics, and simple associations using chi-square at $p < 0.05$ significance level.

Results: Over 80% of these smallholder units had factors that contributed to poor welfare of dairy cattle. These factors included under-size cubicles, small walk-alleys, too high feeding bunks with traumatic edges, too low positioning of neck rails at the feed bunks, sharp objects and edges within the housing units and dilapidated housing structures. The main evidence of poor welfare was injuries on the animals. The body condition score (BCS) of the cows was the main indicator of welfare relating to feeding. Presence of injuries or scars on the skin at various parts of the body was considered a positive indicator of poor welfare either associated with housing structures, management practices or animal interactions. Other causes of poor welfare of the cows were hind-limb tying during milking, teat pulling during hand-milking, more than 24-hour delay before sick cows were treated, and mixing of cattle of different age-groups in the same compartment. Cow-human interaction was poor as evidenced by fearful response and long avoidance distance.

Conclusions: This study concludes that poor welfare of dairy cattle exists in all the smallholder units evaluated, which is mainly caused by improper housing and management. Training of farmers and stockmen on animal welfare issues would therefore be a prerequisite to the improvement of dairy cattle welfare. Research on the physiological response to poor welfare of dairy cows in the smallholder units needs to be carried out to enhance the understanding of the impact of these risk factors on smallholder dairy animals.

P02-002-038

Fitness for transport - how do we assess it?

An observational study of culled dairy cows

Kirstin Dahl-Pedersen¹; Mette Herskin¹; Hans Houe²; Peter T. Thomsen¹

¹Department of Animal Science, Aarhus University, 8830 Tjele, ²Department of Large Animal Sciences, University of Copenhagen, 1870 Frederiksberg C, Denmark

Objectives: In order to prevent pain and suffering during and after transport according to EU legislation, an animal must be fit for transport. Fitness for transport is, however, difficult to assess as not only the current condition of the animal must be assessed but also the potential effect of the transport on the animal's welfare. Both farmers, drivers and veterinarians find this challenging. The legislation offers only very broad and unspecific guidelines and limited research has dealt with the concept of fitness for transport. This study investigates if and how fitness for transport of dairy cows decided to be culled can be assessed.

Materials and Methods: This is an observational study including approximately 400 culled dairy cows transported to slaughter. The cows have been selected by farmers at 23 Danish dairy farms as a part of their normal culling routine and are transported by their regular trucking company to the slaughterhouse. A veterinarian examines the cows before and after transport. Examinations include behavioural and clinical observations e.g. grinding of teeth and locomotion score. Information

regarding the transport e.g. distance and duration is also recorded along with production data such as parity and gestational age. Data analysis will include a comparison of the examinations made before and after transport and potential risk factors for cows unfit for transport will be identified.

Results: The study is expected to generate knowledge about the general condition of culled dairy cows in Denmark and to identify behavioural and clinical manifestations prior to transport, to be used for fitness assessment. All transports are short and national with an average distance around 150 km and an average duration around 200 min. Preliminary results show that more than 1 out of 4 cows receive a higher locomotion score after transport compared to before transport. This suggests that culled dairy cows have an increased risk of becoming lame or more lame by being transported, even if the transports are relatively short.

Conclusions: Depending on the results it may be possible to develop a practical and reliable tool for assessment of fitness for transport. Such a tool could be of use to farmers, drivers and veterinarians helping them to assess which cows are fit for transport and which cows are not, and hence lead to better welfare for cows transported to slaughter.

P02-002-040

The Effect Of Topical Anaesthetic On The Sensitivity Of Scoop Dehorning Wounds In Beef Calves

Charissa Harris ¹ Dominique McCarthy ¹ Sabrina Lomax ¹ Peter White ¹

¹Veterinary Faculty, University of Sydney, Sydney, Australia

Objectives: The objective of this study was to assess efficacy of two newly formulated topical anaesthetics, specifically designed for application to dehorning wounds where excessive haemorrhage is often present, were compared in part 1 of a 2 stage study.

Materials and Methods: In part 1 of the study twenty-one Holstein dairy calves (16 – 20 weeks old) were randomly allocated to (1) scoop dehorning with a post-operative application of a topical anaesthetic powder and (2) scoop dehorning with a post-operative application of an evaporative alcohol / water solvent system spray. Wound anaesthesia was assessed by scoring the behavioural response of calves to wound touch stimulation on a numerical rating scale of 0 to 3. Wound anaesthesia was assessed immediately prior to treatment and 1, 90 and 180 min post treatment.

Based on the results obtained from part 1, a second study was conducted (part 2) as follows; the evaporative spray was compared to a commercially available topical anaesthetic, registered for use on mulesed sheep. Thirty-six Hereford beef calves (16 – 20 weeks old) were randomly allocated to (1) sham dehorning (CON, n = 7); (2) scoop dehorning with a pre-operative nerve block of lignocaine (DLA, n = 7); (3) scoop dehorning with a post-operative application of commercial topical anaesthetic (DTA, n = 7); and (4) scoop dehorning with a post-operative application of novel topical anaesthetic (DNAT, n = 7). Wound anaesthesia was assessed as previously described immediately prior to treatment and 1, 2, 4 and 6 hours post treatment.

Results: The initial study (part 1) showed the calves treated with the evaporative spray responded less severely to touch stimulation at 90 and 180 min post treatment (P < 0.001). Therefore, in part 2 of the study, the evaporative spray was compared to a commercially available topical anaesthetic. There was a significant interaction between time and

treatment (P < 0.001) with CON calves displaying no to mild responses at all time points and all dehorned groups displaying increasing responses, yet not differing from one another.

Conclusions: The effect of topical anaesthetic is comparable to that of a nerve block of lignocaine and may be a more practical option for on farm use. In extensively managed production systems scoop dehorning of beef cattle reduces the risk of injury to stock workers and other cattle and decreases bruise trim at slaughter. As a result of distances, animal numbers and expenses, impracticality of currently available pain relief prevent widespread uptake for routine husbandry operations. Effective anaesthetic that can be applied topically would offer a more feasible option for producers to address the post-operative pain of dehorning.

Reactivity variation over time of beef cows undergoing weaning

Tisa Echevarria Leite ¹ Leonardo S. Dall Asta ² Zilah Maria G. Cheuiche ³ Mara Francelina S. Dall Asta ¹

¹Universidade Federal do Pampa, Dom Pedrito, ²Universidade Federal do Pampa, Uruguaiana, ³Associação Brasileira de Hereford e Braford, Dom Pedrito, Brazil

Objectives: This study aimed to verify the continued responsiveness of beef cows, which were subjected to the stress of weaning, against a management practices commonly used in the farms, how to be restrained in a squeeze chute.

Materials and Methods: The experiment was conducted in Dom Pedrito, RS, Brazil, using 49 cows Braford, Brangus, Hereford and Angus breeds, raised in extensive system, exclusively on natural pasture. The animals were evaluated in three stages, with an interval of two months between each evaluation; by using the composite score (EC). The composite score was calculated based on the evaluation of animal mobility (1 = calm, 2 = active, 3 = restless, 4 = disturbed and 5 = very upset) and audibility and intensity of breath, vocalization, kicks and tension of animals during their stay in balance. Animal composite score ≤2 were considered non-reactive and ≥3 were considered reactive. The data were submitted to ANOVA in SPSS18® Program.

Results: The composite score of reactivity of the cows showed a significant variation (P < 0.01), according to the time of the inspection, with the frequency of reactivity classification measured by the composite score in the three periods distributed as follows: 79.59% of cows classified as non-reactive and 20.41% classified as reactive in the first assessment, 97.96% classified as non-reactive and 2.04% as reactive in the second evaluation and 95.92% as non-reactive and 4.08 as reactive in the third assessment.

Conclusions: We can conclude that the reactivity of beef cows submitted to weaning has a tendency to decrease as time passes after it occurs. More work is needed to verify the repetition of results in longer periods.

Animal Welfare

P02-002-042

Comparing the effects of intranasal and intramuscular administration of xylazine on the pain response of calves

Sabrina Lomax¹, Dominique McCarthy¹, Peter White¹¹Faculty of Veterinary Science, The University of Sydney, Sydney, Australia**Objectives:** This study aimed to:

1. compare the effects of intramuscular and intranasal administration of the alpha-agonist xylazine on time to and depth of sedation in holstein dairy calves
2. assess the analgesic effects of intramuscular and intranasal administration of xylazine on the pain response of dairy calves to caudatey disbudding

Materials and Methods: 16 Holstein heifer calves (62 – 100 kg) were randomly allocated to (1) caudatey disbudding (D, n = 4); (2) intramuscular administration of xylazine (0.1 mg/kg) followed by caudatey disbudding (IMX, n = 6); and (3) intranasal administration of xylazine (0.3 mg/kg) followed by caudatey disbudding (INX, n = 6). Clinical indications of onset and duration of sedation were observed. These included muscle relaxation, ptialism, lowering of the head and eyelids, recumbency, reduced respiration and heart rate and delayed or absent alertness. Calf response to disbudding was scored using a scale of 0 – 3 (0 = no reaction; 1 = minor response, slight eye widening, ear flick; 2 = moderate response, eye widening, ear flicks, head movement, vocalization; and 3 = severe response, vocalization, full head movement, escape attempt). A latency to move test was conducted 20 min and 45 min post treatment to test calf response to human approach. The observer took 0.5m steps towards the resting calf, and the distance (m) at which the calf moved to avoid the human was recorded. It was hypothesized that increased sedation would equate to a closer approach distance.

Results: Onset of sedation was recorded at 5 min for both IMX and INX calves. IMX and INX calves displayed all clinical indications of sedation. There were no observed differences between IMX and INX calves in terms of the degree and duration of sedation. There was a significant effect of treatment on the behavioural response of calves to disbudding ($P = 0.02$). D calves had significantly greater response scores than IMX and INX calves. There was a significant effect of treatment on latency to move ($P = 0.01$). D calves were more sensitive to human approach, as indicated by the greatest distance (3.7m). INX had the slowest response of 1.4m, significantly shorter than IMX (2.2m).

Conclusions: These results indicate that intranasal delivery of xylazine at a dose of 0.3 mg/kg resulted in fast and effective sedation and analgesia of calves as compared to intramuscular administration. Xylazine administered in both forms resulted in significant analgesia for calves undergoing caudatey disbudding. This presents a potential method for on-farm analgesia to manage perioperative pain in livestock.

Impact of oral meloxicam on circulating physiological biomarkers of stress and inflammation in beef steers after long distance transportation

Nicholas Van Engen¹, Johann Coetzee¹, Terry Engelken¹, Matthew Stock²¹VDPAM, Iowa State University, Ames, ²Merck Animal Health, New Jersey, United States

Objectives: Transportation stress can result in significant economic losses to producers due to decreased animal productivity and increased medication costs associated with sickness such as bovine respiratory disease (BRD). Meloxicam (MEL) provides pain relief and anti-inflammatory effects in cattle for several days after a single oral treatment. Our hypothesis was that MEL administration before shipping would reduce the impact of long distance transportation on circulating physiological biomarkers of stress and inflammation in beef steers.

Materials and Methods: Ninety-seven beef steers were blood sampled for baseline biomarker determination and then randomly assigned to receive either 1 mg/kg MEL (n = 49) or a placebo (CONT) (n = 48) *per os* prior to a 1,316 km transportation event lasting approximately 16 h. Calves were then blood sampled on arrival and 5 d later. Changes in the hemogram, circulating plasma proteins, total carbon dioxide (TCO₂), fibrinogen, substance P (SP), cortisol, haptoglobin (Hp)-matrix metalloproteinase-9 (MMP-9) complexes and tumor necrosis factor alpha (TNF α) between treatments over time were compared using a Mixed Effects Model with statistical significance designated as $P < 0.05$. ANCOVA was conducted to assess the relationship between circulating MEL concentrations and biomarker changes over time.

Results: An increase in neutrophil, platelet, monocyte, white blood cell and red blood cell counts occurred after transportation ($P < 0.0001$) and a decrease in lymphocyte count was observed ($P < 0.0001$). MEL treatment reduced the stress-induced neutrophilia ($P = 0.0072$) and circulating monocyte count ($P = 0.013$) on arrival. Mean corpuscle hemoglobin ($P = 0.05$), mean corpuscle volume ($P = 0.05$) and lymphocyte count ($P = 0.05$) was also greater in the CONT calves compared with MEL calves after transportation. Furthermore, HP-MMP-9 complexes, TCO₂, TNF α , plasma proteins and SP increased and cortisol decreased after shipping ($P < 0.01$). MEL treatment tended to reduce serum cortisol concentrations ($P = 0.08$) and there was evidence of a time-by-treatment interaction ($P = 0.04$). An inverse relationship between plasma MEL concentrations and circulation cortisol concentrations ($P = 0.002$), neutrophil ($P = 0.04$) and basophil counts ($P = 0.03$) was also observed.

Conclusions: The results suggest that meloxicam administration may reduce the impact of long-distance transportation on circulating physiological biomarkers of stress and inflammation in beef calves on arrival to the feedyard.

Comparative time, behavior and economic differences associated with calves receiving a pour-on vs. an intravenous product

David Amrine¹, Siddhartha Torres²¹Professional Beef Services, Manhattan, ²Merck Animal Health, Madison, United States

Objectives: Intravenous (IV) route of drug administration requires proper animal restraint, familiarity with bovine anatomy, and potentially increases stress, time and costs compared to pour-on administration.

The objectives of this study were: 1) Determine differences in time required to administer a pour-on saline solution compared to inject IV; 2) Measure behaviors during and immediately post saline administration and evaluate for potential differences; and 3) Determine economic costs associated with both a pour-on saline and an injectable saline solution based on the time and supplies necessary for administration.

Materials and Methods: One hundred beef crossbred calves were selected and randomized to treatment ((IV) or Pour-On (POUR)) based on chute order prior to the study. Each calf was moved into a processing chute and restrained using a head gate. Calves randomized to POUR received 18 ml of sterile saline on their back to simulate the administration of a pour-on product. Cattle assigned to IV were additionally restrained using a halter to fasten their head to the chute and allow access to the jugular vein prior to saline IV injections. The time calves were restrained in the head gate was recorded and 3 scoring systems (vocalization score, chute score, and exit score) were used to capture potential changes in behavior/stress associated with treatment. Costs associated with labor and materials for each treatment were estimated.

Results: Results showed a reduction in chute time per animal of 36.45 seconds comparing IV injection (53.61 s) vs. pour-on (17.16 s). Estimated labor cost per animal were \$0.54 USD less for POUR vs. IV calves. Cost of material needed for IV administration (syringe and needle) was estimated at \$0.70 per animal. The total cost savings achieved by pour-on administration compared to an IV injections was estimated at \$1.24 (\$0.54 [labor] + \$0.70 [material] = \$1.24 [labor + material]). Behavior analysis showed calves receiving a pour-on administration had a higher ($P < 0.05$) probability of not vocalizing while in the chute and having a normal chute score.

Conclusions: The pour-on administration provided a total cost savings of \$1.24 (\$0.54 + \$0.70) per animal compared to an intravenous injection. Animal vocalization and excessive movement during processing at the chute has been associated with calves experiencing stressful conditions. Data from the present study indicate that calves receiving a pour-on administration were less stressed while in the chute compared to those receiving intravenously administered saline.

Benchmarking Locomotion Score in 114 Dairy Farms in Northwestern of Spain

Yolanda Trillo¹; Sonia Verdes²; Juan J. Becerra²; Pedro Herradon²; Ana Pena²; Luis A. Quintela²

¹Reproduction and Obstetrics, Veterinary Medicine - Veterinary Medicine - University of Santiago de Compostela, ²Reproduction and Obstetrics, Veterinary Medicine - University of Santiago de Compostela, Lugo, Spain

Objectives: To describe locomotion scores and lameness prevalence as well as showing opportunities for improvement on locomotion scores through benchmarking in 114 dairy farms in the Northwest Spain (Galicia's region).

Materials and Methods: Farms (n=114) were sampled during 2015. All free-stall barns with cubicles randomly selected by local veterinarians. Herd size ranged from 20 to 244 cows however, the median across farms was 43 cows (Holstein).

Measurements were collected only once on every farm around the time of the first milking (7 to 9 am).

Cows were scored in the feeding alley for locomotion between 1 (sound) and 5 (severely lame) according to guidelines by Sprecher et al. (1997) assessment. Lameness cows were under locomotion score 3, 4 and 5.

Results were described through percentage of each score by farm, overall media, standard deviation (SD), quartiles: first (Q_1 : 25% data), second (Q_2 : 50% data, median), third (Q_3 : 75% data); and, variation across farms was measured by the Interquartile Range (IQR: $Q_3 - Q_1$; data dispersion).

Results: Percentage of each locomotion score among the 114 sampled farms is reported by Q1 - Q2 - Q3, IQR and media (minimum - maximum), as follow:

% Score 1: 47 - 56 - 65, 18 and 65 (23 - 100).

% Score 2: 11 - 15 - 24, 13 and 24 (0 - 57).

% Score >2: 2 - 5 - 8, 6 and 11 (0 - 60).

The average for each score is not far from the recommended ones (70% score 1, 20% score 2 and < 10% score 3 - University of Wisconsin-Madison). However, the variation across farms was high.

Regarding the data published in other areas of the world and independent of the scoring system, the average prevalence of lame cows is relatively small (Europe or USA range from 14% to 31% [(Wells et al., 1993; Whay et al., 2003; Sarova et al., 2011)]. However, due to the high variation observed across our farms, the average itself does not show the real situation.

Conclusions: Even the lameness prevalence of Northwest Spanish farms was similar to other regions as well as close to the recommendations, there was a high variation across farms. Therefore, the average value may not be a good measurement to evaluate farms performance among different studies, while other descriptive statistics suggested in this study, as Quartiles or IQR, may allow opportunities to improve lameness prevalence within and across farms.

White Blood Cell Count after Disbudding in Calves Treated with Photodynamic Therapy

Edlen A. Medeiros¹; Bruna S. Barbosa²; Carolina dos Anjos²; Fábio P. Sellera²; Ronaldo G. Gargano²; Lilian R. M. Sá³; Luciana A. Lopes⁴; Fernando J. Benesi²; Rogério B. Santos¹; Fabio C. Pogliani^{2,2*}

¹Paulista University, ²Internal Medicine, ³Animal Pathology, University of São Paulo, São Paulo, ⁴Nupen - Research and Education Center of Photo Therapy in Health Sciences, São Carlos, Brazil

Objectives: Photodynamic therapy (PDT) is a procedure that has been investigated for the treatment of microbial diseases, with no adverse effects. The antimicrobial properties from PDT combine a harmless photoactivatable dye with visible light and molecular oxygen. Its mechanism of action is based on the excitation of photosensitive substances by light at proper wavelengths, resulting in the formation of reactive oxygen species which will determine selective death of microorganisms. The general purpose of our research was to investigate the effect of PDT on calve's white blood cell count (WBCC) after disbudding, improving animal welfare.

Materials and Methods: Twelve male Holstein calves, four weeks old, disbudded by hot iron were used in the study. Local anesthesia was performed with lidocaine hydrochloride 2%. The cornual branch of the zygomaticotemporal nerve was blocked associated with infiltrative anesthesia around the cornual button. After hair clipping and antiseptics with 2% chlorhexidine, bilateral cauterization of germinal buds was made. For pain relief after disbudding, we administered metamizol sodic (25mg/kg, SID) during three days.

The animals were divided into three different treatment groups:

- 1) Control (ointment with zinc oxide) - 4 calves;
- 2) PDT: visible light - Red LED ($\lambda = 660\text{nm}$, 350mW, 4J) associated with a photosensitizer -methylene blue (0.01%) - 4 calves;
- 3) Visible light - Red LED ($\lambda = 660\text{nm}$, 350mW, 4J) - 4 calves.

Only one treatment with zinc oxide ointment, PDT and red LED was made, according to the described groups, immediately after hot iron disbudding.

Blood samples were collected for WBCC evaluation in seven different times: 1h before disbudding; 2h and 4h after disbudding; 3, 7, 14 and 21 days after disbudding.

Statistical analysis was made with Tukey's test ($p < 0,05$) using Minitab Statistical Software.

Results: According to our results, we haven't found statistical differences in the total leukocyte count among the different groups within the same time, as well as in the total number of neutrophils, eosinophils, basophils, lymphocytes and monocytes in any of the studied periods when different treatments were compared.

When the comparisons were made among the different times but within the same group, there was no difference as well.

Local burn injuries could lead to systemic alterations in WBCC if secondary infections and/or severe inflammation were present, but, in our study, there were no animals with systemic responses to them. Therefore, no alterations in WBCC were found regardless to the studied group.

Conclusions: We concluded that there was no difference in the WBCC in hot-iron disbudded calves, regardless the treatment group. Therefore, the WBCC did not present itself as an accurate indicator for acute inflammation in disbudded calves when local burn injuries remain without complications. Further studies are needed to assess the advantages of PDT as a practical and effective treatment after hot-iron disbudding in calves and to elucidate the potential role of PDT as wound healing promoter, improving the animal welfare after such procedure.

Animal Welfare

P02-002-047

Prevalence and Risk Factors for Hock Lesions in Swedish Dairy Cows

Lisa Gustafsson^{1,2} Ann Nyman² Elisabeth Bagge³ Ulf Magnusson¹ Karin Persson Waller^{1,2}

¹Department of clinical sciences, Swedish University of Agricultural Sciences, ²Department of animal health and antimicrobial strategies, ³Department of bacteriology, National Veterinary Institute, Uppsala, Sweden

Objectives: Hock lesions (HL) indicate poor cow environment and are often used in animal welfare assessment protocols. The lesions cause pain and discomfort, are associated with lameness, increased milk somatic cell counts (SCC) and culling rates, and are common in several countries. Few studies have, however, been performed in Sweden. Risk factors have been identified, but the etiology is still not fully understood. The objectives of the study were to investigate the prevalence of HL in Swedish dairy herds, to identify herd- and cow-level risk factors associated with HL and to analyze associations between HL and mastitis, claw disorders and culling.

Materials and Methods: A random sample of 100 Swedish dairy herds were visited once during winter/early spring 2014 or 2015. Included herds had free-stalls, 50-210 cows, milking parlor and were affiliated with the Swedish official milk recording scheme. Every second to third cow was examined during milking and registered as having no HL (no visual skin damage or hair abrasion), mild HL (hair loss) or severe HL (skin wound or evident swelling) on the outside of the hock visible when standing in the milking parlor. Examined cows were also assigned a hygiene score based on hind limb and udder cleanliness. Additional information on individual cows, herd management and cow environment factors was obtained both on farm via registrations and a pre-formed questionnaire, and from the official milk recording scheme. Investigated cow level risk factors included age, breed, days in milk, milk yield, milk urea levels, milk SCC, hygiene score and claw disorders. Veterinary-treated cases of clinical mastitis 30 days before and after the visit, and culling up to three months after the visit were registered to investigate their possible association to HL. Herd level risk factors investigated were herd size, production system (organic or non-organic), stocking density, cubicle size, bedding material, barn cleaning routines, claw trimming routines, average milk production level, breed, bulk tank milk SCC and urea levels, feeding routines, length of pasture period and registered veterinary treated diseases (with special regard to mastitis, claw disorders and feed-related disorders).

Results: The total cow prevalence of HL was 74% (2582 of 3775 cows), and the majority (91%) of the lesions were mild while 9% of the HL were severe. The within-herd prevalence of HL ranged between 24-100% (average 73%), while the within-herd prevalence of severe lesions ranged between 0-30% (average 6%). Several herds had a high (50-100%) proportion of mild lesions but no, or very few, cases of severe lesions, while other herds had high proportion of both severe and mild lesions. The combination of a high proportion of severe HL (>10%) and a low proportion (<50%) of mild lesions was unusual but seen in a few herds. Potential associations between HL and the risk factors are analyzed using univariable and multivariable regression models and these results will be presented at the congress.

Conclusions: The results indicate that the prevalence of HL in Swedish dairy herds is similar to other countries with equal production systems. Thus, HL is an important health problem also in Sweden. The large within-herd variation in prevalence and proportions of mild and severe HL indicate that herd factors may be important for the occurrence and severity of the lesions. If identified, these factors could be an important aid

in reducing herd prevalence of HL. Longitudinal and microbial studies of HL are of interest to increase understanding on why and how the lesions develop, persist and heal, and will also be performed within the project.

Developing a farmers evaluation form to create awareness on the behaviour and pain management of Belgian Blue cows after a caesarean section

W.A. Buijsse^{1,*}

¹Herkauwerspraktijk "De Overlaet", Oss, Netherlands

Objectives: The use of non-steroidal anti-inflammatory drugs (NSAID) during a caesarean section is not a common practice among beef farmers with Belgian Blue cows. The objective of this field case study was to create and test an evaluation form for beef farmers on the behaviour and pain management of Belgian Blue cows after caesarean section using a NSAID. With this form awareness can be created on behaviour related to pain after a caesarean section in beef cows. This study was initiated and executed by a veterinary practice in the Netherlands.

Materials and Methods: A large veterinary practice in the south of the Netherlands enrolled their clients randomly in this field experience. The cows were operated using a standard operating procedure performed by all veterinarians in this practice. A NSAID (meloxicam 20mg/ml, 2.5ml/100kg subcutaneously) was administered by the veterinarian directly after the operation. To evaluate the effect of the NSAID on the behaviour a form was created. This farmer's evaluation form had to be practical and easy to use for a good response rate and reliability. Important parameters for a farmer are the lying or standing time, lying-standing bouts, feed intake, the suckling activity of the calf (in case there is no separation), the colostrum and milk production and the body temperature (°C) of the cow. In this field case study the following parameters had to be observed by the farmer: lying time, lying-standing bouts, feed intake of the cow and suckling time of the calf. The scores were divided in high, average and low. A table was present on the form with the four parameters on the y-axis and the three scores on the x-axis, by doing this the farmer could easily put a cross-mark in the cell of his choice. The observation period was day 1 and day 2 after the surgery. There was one open question on the form which stated "what is your general impression of the cow in the first two days after the caesarean with the NSAID treatment". Hereby the farmer could share his experience of the treatment. The farmers in this trial did not use a NSAID during a caesarean surgery previously.

Results: After the trial period (August 2015 until October 2015) eighteen caesarean sections were evaluated and these operations were done by 4 different veterinarians on 5 different farms. The scores high, average and low of the lying time on day 1 and day 2 combined were respectively 2, 18 and 16. The scores high, average and low of the lying-standing bouts on day 1 and day 2 combined were respectively 0, 23 and 13. The scores high, average and low of the feed intake on day 1 and day 2 combined were respectively 22, 12 and 2. The scores high, average and low of the suckling time of the calf on day 1 and day 2 combined were 17, 9 and 1. The total percentage of the scores on this evaluation form was 29.9% high, 45.3% average and 24.8% low. The average temperature of the cows on day 1 was 39.0 °C with a standard deviation of 0.5. The average temperature of the cows on day 2 was 38.8 °C with a standard deviation of 0.4. The open question on the form was used by every farmer. The general opinion was very positive; a quick recovery of the

cow with a good feed intake and suckling activity of the calf was noticed.

Conclusions: The response rate of this evaluation form was high; all the farmers who were asked to fill in this form returned it with every questions answered. A lot of the parameters were scored with average, this could be a sign of low interest of the farmer and possible poor reliability. The open question was answered on every form, so the farmers were motivated to share their positive experiences. Beef farmers were more aware of the behaviour of their cows after a caesarean section and the effects of pain management on this behaviour. A practical and easy to use evaluation form can serve as an excellent tool to achieve this purpose.

P02-002-049

A Pilot Study to Investigate the Feasibility of Behavioural Monitoring of Periparturient Cows and Calves on a Commercial Dairy Farm in Scotland.

Nicola Gladden^{1,*} Emma Strazhnik² Allison McGann³ Lorenzo Viora¹ Dorothy McKeegan² Kathryn Ellis¹

¹Scottish Centre for Production Animal Health and Food Safety, University of Glasgow School of Veterinary Medicine, ²Institute of Biodiversity, Animal Health and Comparative Medicine, University of Glasgow, ³Glasgow University Veterinary School, University of Glasgow School of Veterinary Medicine, Glasgow, United Kingdom

Objectives: Dystocia is a painful event for both the cow and the calf; however, there is a paucity of research in this area, particularly regarding the use of analgesia at the time of calving. The current project aims to investigate the use of non-steroidal anti-inflammatory drugs (NSAIDs) in both the cow and the calf at calving.

Results from a preliminary feasibility project investigating cow and calf behaviour post-partum undertaken in the summer of 2015 will be presented. The practicalities involved in performing such a project on a commercial dairy farm were assessed. A 700 cow herd in Scotland has been recruited for this study.

Materials and Methods: A camera recording system monitored cow and calf behaviours after calving. The degree of assistance required for calving was graded by the farm staff using an established dystocia scoring system (1=no assistance; 2=mild repositioning required but not excessive traction; 3=severe traction required; 4=veterinary assistance or caesarean section). Grade 4 calvings were excluded from the study. The observer was blinded to the degree of assistance required.

Calf study

Four cameras covering the calf pens monitored calf behaviour for the first 48hours after calving. Calves were moved out of the calving pen and into a calf pen as soon as practicably possible after calving. Any time spent with the dam was captured by cameras in the calving pen.

Video of the behaviour of 10 assisted calves and 10 non-assisted calves was analysed. An informal interval analysis performed at the beginning of the study indicated that observing calf behaviour for 5 minutes every other hour was an appropriate sampling interval.

Cow study

The same camera system (using 6 cameras) covered the calving and post-partum pens to monitor cow behaviour for 48hours post-partum.

Due to the longer period of time spent setting up the camera system in the calving and post-partum pens, cows were videoed over a shorter period than calves (2 weeks compared to 8 weeks). Cow behaviour was

analysed by a different observer using continuous observation for the first 2 hours post-partum. From 2 to 48 hours post-partum, behaviour was analysed using interval sampling; cow behaviour was observed for 10 minutes every hour.

Results:

Calf study

Behavioural analysis of calves indicated that the greatest proportion of time was spent exhibiting lying behaviours. This did not differ significantly between assisted calves and non-assisted calves ($89.78 \pm 3.98\%$ and $88.99 \pm 6.23\%$ (mean \pm sd) respectively; $p=0.98$).

Assisted calves did not participate in play behaviours as much as non-assisted calves. Non-assisted calves not only spent double the proportion of time showing play behaviour than assisted calves, ($0.81 \pm 1.45\%$ and $0.29 \pm 0.66\%$ respectively) with a degree approaching significance ($p=0.09$), they also exhibited more variation in play behaviours than assisted calves.

Cow study

Behavioural analysis of the cows indicated that cows with unassisted calving spent a greater proportion of time lying down on the day of calving than the day after calving. Cows that had an assisted calving showed more similar proportions of time spent lying down on both day 1 and day 2 post-partum. Due to the small sample size ($n=4$) no statistical conclusions can be made.

Conclusions: Although data were limited, the intended aim was achieved. It is possible to perform a study such as this on a commercial dairy farm. Further work will be undertaken during 2016 with an intervention study using NSAIDs at the time of calving in both cow and calf. Behavioural analysis using the model established during this study will be performed, as will assessment of physiological parameters and analysis of farm recorded data.

This study aims to address the lack of research in this area and in the future enable practitioners to advise their farm clients regarding analgesic use to improve the welfare and production of both cows and calves.

Characterization of Cow Activity Behavior During the Transition Period

Robert Van Saun¹, Ernest P. Hovingh¹

¹Department of Veterinary & Biomedical Sciences, Pennsylvania State University, University Park, United States

Objectives: Previous research has shown cows experiencing postpartum disease events had lower feed intake in the weeks prior to calving compared to cows with no abnormal health events. More recent research has implicated alterations in cow feeding behaviors as an underlying cause of the feed intake decline and suggest prepartum feed intake could be used as an indicator of increased risk for postparturient disease. There are limited data documenting cow activity behavior during the transition period. The objective of this study was to characterize cow activity behavior during the dry period and early lactation of healthy animals.

Materials and Methods: A total of 178 dairy cows were continuously followed over a period of 6 months on a commercial 750-cow dairy from the time of entry into the dry cow group (average 60 d dry) through 3 weeks postpartum. Three-axis accelerometers (HOB0 logger, ONSET

Corp.) were placed on the hind leg of each cow, just above the fetlock joint, to record standing or lying position in 5 minute intervals. Cows were moved into the dry pen weekly and transferred to the close-up pen approximately 3 weeks prior to expected calving. Cows imminently calving were moved into the maternity pen. Heifers were housed in a single separate pen from cows and moved into the maternity at calving. After calving all cows were transferred to then the fresh cow pen within 6 hours. Dry, close-up and fresh pens were well-designed free stalls with deep sand bedding. Maternity pen was loose housing with straw bedding. All health observations, events and treatments were recorded using a computerized recordkeeping system (DairyComp 305®). Data from 84 cows with no abnormal health events were used for this analysis. Accelerometer data were transformed into behavioral activities of standing and lying times (hr/d), lying bouts per day (n), and average lying time per day (hr). Upper and lower 1% quantile data were censored to remove extreme values. Behavioral activities were analyzed by analysis of variance using repeated measures and regression modeling to account for parity (1st, $\geq 2^{\text{nd}}$), pen, time or day relative to calving, and calving month.

Results: Fresh cows spent less ($P<.0001$) time lying (10.3 ± 1.6 hr) compared to dry cows (12.8 ± 1.7 hr) and times did not vary ($P=.2$) by parity, though there was a tendency ($P=.08$) for cows to have longer times compared to heifers in dry and fresh periods. Number of lying bouts and average lying time were influenced by dry vs. fresh period ($P<.0001$, $.0001$), age ($P<.0001$, $.0001$), although there was a significant ($P<.0002$, $.01$) interaction between the two. Cows had less lying bouts and nearly twice the average lying times in all periods compared to heifers. Heifers increased their lying bouts ($n=8.7, 9.2, 10.2$) and decreased average lying time ($2.4, 2.0, 1.0$ hr) from dry to close-up to fresh periods, respectively. Day relative to calving influenced ($P<.0001$) lying time in the dry, close-up and fresh pens. In the dry pen, cows increased ($+0.03$ hr/d, $P<.0001$) lying time while heifer total lying time did not change. Cow lying time was increased by less lying bouts ($P<.0001$) with longer ($P<.0001$) average lying times. Both cows (-0.034 hr/d, $P=.007$) and heifers (-0.057 hr/d, $P=.0003$) decreased their lying time in the 3 wk prior to calving. Average lying time per bout was reduced in both heifers ($P<.0001$) and cows ($P=.009$). Fresh pen lying time increased ($+0.03$ hr/d, $P=.03$) in heifers and tended to increase in cows ($+0.02$ hr/d, $P=.09$). Cows first moved into close-up and fresh pens had decreased total lying time ($P=.01$) and average lying time per bout ($P=.0035$) in the 4 days upon pen entry. Greater negative effects occurred in the fresh pen.

Conclusions: These data show patterned changes in activity behaviors in healthy cows and heifers during transition, though measures are highly variable among individuals. Though cows and heifers have similar total lying times, different patterns of lying behavior occur in comingled cows and heifers during transition. Lying time was reduced for 4 days whenever a cow changed pens. These data provide some standards for evaluating transition cow behaviors in a commercial dairy with good cow comfort.

Unterschleißheim, Germany, Unterschleißheim, Australia, ³Department of Veterinary Sciences, Chair of Anatomy, Histology and Embryology, Faculty of Veterinary Medicine, Ludwig-Maximilians-University Munich, Germany, ⁴Department of Veterinary Sciences, Chair of Animal Welfare, Ethology, Animal Hygiene and Animal Husbandry, Faculty of Veterinary Medicine Ludwig-Maximilians-University Munich, Germany, Munich, Germany

Objectives: Worldwide, the mortality of calves during the first weeks of life is still 10 to 15%. More than 80% of the calf losses can be traced back to farm-specific management problems. An improved colostrum management can help to reduce these calf losses. The objective of this study was to evaluate the IgG-Status of newborn calves in Germany.

Materials and Methods: Using a survey, data relating to the farms were collected such as the number of animals, type of housing, illnesses in the barn, especially diarrhea, and specific calf-related data such as breed, parity of the dam, calving difficulties, age of calf at blood withdrawal, time spent with the dam and the time after birth, quantity and method in which the colostrum was fed. Additionally, data regarding colostrum monitoring were recorded. The Immunglobulin G (IgG) content of altogether 1242 blood samples (taken between the 36th to the 96th hour of the calves' life) from 296 farms all over the country were taken from February to September 2015 and were analyzed using a Sandwich ELISA (Erhard et al., 1995). To trace back the health status of the examined calves within the first eight weeks of life the farmers were asked to complete another questionnaire concerning the occurrence of diarrhea and Pneumonia and the time at which the calves fell ill.

Results: The results show that nearly 23% of the calves were completely (failure of passive transfer, FPT, IgG-concentrations < 5 mg/ml serum, n= 284) and 36% partly (partial failure of passive transfer, pFPT, IgG-concentrations 5-9.9 mg/ml serum, n= 450) undersupplied with IgG. Only 41% of the tested calves showed sufficient IgG-concentrations (> 10 mg/ml, n= 508).

The number of lactations effected the serum IgG levels of the newborns ($p < 0.001$, Pearson correlation $R = 0.149$) slightly positive.

The method by which colostrum was fed did not significantly influence the calves' serum IgG concentrations. The Median IgG-levels ranged from 8.3 mg/ml (bottle), over 8.4 mg/ml (bucket) to 8.5 mg/ml in the drenched calves. The amount of colostrum fed during the first feeding had a significant influence ($p < 0.001$, Pearson correlation $R = 0.144$) on the serum IgG concentrations of the calves. There was no significant difference ($p = 0.182$) between the calves which became diarrhea and those without diarrhea in the first weeks of life. However, calves with diarrhea showed higher IgG-concentrations (Median with diarrhea: 10.05 mg/ml; without diarrhea: 8.05 mg/ml). The same trend could be seen with Pneumonia. Calves with Pneumonia had also higher IgG-levels (Median with Pneumonia: 11.10 mg/ml; without Pneumonia: 8.65 mg/ml, $p = 0.490$).

Conclusions: In conclusion there are still needs for clarification and action concerning the management of calf rearing in Germany and most likely in other countries as well.

This study was initiated and conducted in cooperation with MSD Animal Health, Germany.

Novel methods to alleviate the peri-operative and post-operative pain of amputation dehorning in beef calves

Dominique Mccarthy ¹; Sabrina Lomax ¹; Peter White ¹

¹Faculty of Veterinary Science, The University of Sydney, Sydney, Australia

Objectives: The aim of the study was to assess the efficacy of a pre-operative buccal sedative / non-steroidal anti-inflammatory drug (NSAID) formulation, a pre-operative cryo-anaesthetic (CA) and a post-operative topical anaesthetic (TA), for pain alleviation in calves undergoing amputation dehorning. Efficacy was evaluated through assessment of behaviour, inflammatory indicators and wound healing.

Materials and Methods: The experimental protocol was conducted under institutional animal ethics committee approval. Seventy-five Hereford calves, 5 months of age, were randomly allocated to (1) sham dehorning / control (CON, n = 15), (2) amputation dehorning with a pre-operative local nerve block of lignocaine (currently perceived as industry best practice) (DL, n = 15), (3) amputation dehorning with pre-operative application of a cryoanaesthetic (DC, n = 15), (4) amputation dehorning with pre-operative administration of a buccal sedative / NSAID (DSN, n = 15), and (5) amputation dehorning with post-operative application of a TA (DTA, n = 15). Adverse calf behaviour during the dehorning procedure was scored on a numerical rating scale as a measure of peri-operative pain. Calf behaviour was also monitored for 6 hours post treatment. Events that were recorded include head shaking, ear flicking, tail flicking, head turning, leg to head pawing and head rubbing. States that were recorded include neck extension, scratching, normal lying, abnormal lying, normal standing, abnormal standing, normal walking and abnormal walking. The frequency of events and states were recorded and additionally the time length of states was recorded. Measurements for assessment of inflammation and wound healing of the horn area were taken immediately prior to treatment and 1, 3 and 7 days post treatment. Inflammation and wound healing were assessed via infrared thermography, measurement of wound contraction, plasma haptoglobin and observational scoring of the horn area on a numerical rating scale.

Results: DL and DC calves displayed less adverse behaviour during the dehorning procedure compared to D, DSN and DTA calves ($P < 0.05$). In the 6 hours following treatment, DSN and DTA calves displayed significantly less pain related behaviour than DL and DC calves ($P < 0.05$). Wound temperature and contraction varied across days ($P < 0.05$). There was no treatment effect on wound temperature or contraction. Healing scores significantly increased on day 7 ($P < 0.05$). There was no significant treatment effect on wound healing score. DSN calves had overall reduced concentrations of haptoglobin compared to all other dehorned calves ($P < 0.05$).

Conclusions: The nerve block of lignocaine and the CA reduced adverse behaviour during the dehorning procedure, suggesting that they both mitigate peri-operative pain. CA is quicker and easier to use than administering nerve blocks and therefore may be a more practical option for on farm use. Buccal sedative / NSAID and TA reduced acute pain related behaviour during the 6 hours following treatment. In addition, the buccal sedative / NSAID reduced haptoglobin concentrations, suggesting a reduction in inflammation and associated pain. Buccal and topical delivery of analgesia may provide farmers with feasible options of providing pain relief for dehorning.

P02-002-053

Efficacy of a topical anaesthetic (TA) and a buccal non-steroidal anti-inflammatory drug (NSAID) for pain relief of surgically castrated calves.

Dominique Mccarthy¹, Sabrina Lomax¹, Peter White¹¹Faculty of Veterinary Science, The University of Sydney, Sydney, Australia

Objectives: To investigate the effect of a topical anaesthetic (TA) and a buccal non-steroidal anti-inflammatory drug (NSAID), alone and in combination, on post-operative behaviour, scrotal temperature, scrotal size, plasma haptoglobin and wound healing of beef calves following surgical castration. This investigation aimed to assess the use of TA and buccal NSAID as effective and practical forms of pain relief for incorporation into routine farm management.

Materials and Methods: The experimental protocol was conducted under institutional animal ethics committee approval. Fifty Angus bull calves, 3 months of age, were randomly allocated to (1) sham castration / control (CON, n = 10), (2) surgical castration (C, n = 10), (3) surgical castration with pre-operative administration of a buccal NSAID (CN, n = 10), (4) surgical castration with post-operative application of a topical anaesthetic (CTA, n = 10) and (5) surgical castration with pre-operative administration of a buccal NSAID and post-operative application of a topical anaesthetic (CNTA, n = 10). Animal behaviour was monitored for 6 hours post treatment. Events that were recorded include tail flicking, head turning, foot stamping, kicking and easing quarters. States that were recorded include hind leg extension, scratching, normal lying, abnormal lying, normal standing, abnormal standing, normal walking and abnormal walking. The frequency of events and states were recorded and additionally the time length of states were recorded. Measurements for assessment of inflammation and wound healing of the scrotal area were taken immediately prior to treatment and 1, 2 and 7 days post treatment. Inflammation and wound healing were assessed via infrared thermography, measurement of scrotal size, plasma haptoglobin and observational scoring of the scrotal area on a numerical rating scale.

Results: In the 6 hours following treatment, CN, CTA and CNTA calves displayed significantly less pain related behaviour than C calves ($P < 0.05$). Both average and maximum scrotal temperature varied across days ($P < 0.05$). There was no treatment effect on scrotal temperature. Scrotal size of castrated calves increased in the following 2 days post treatment and then decreased on day 7 ($P < 0.05$). Healing scores significantly increased on day 7 ($P < 0.05$). Administration of the buccal NSAID and the TA had no effect on scrotal size or healing score. CN and CNTA calves had overall reduced concentrations of haptoglobin compared to C and CTA calves ($P < 0.05$).

Conclusions: Reduced acute pain related behaviour indicates that both buccal NSAID and TA ameliorate the post-operative pain of surgical castration in beef calves. Lowered haptoglobin concentrations of CN and CNTA calves suggest that buccal NSAID reduces the inflammatory response to surgical castration. Both buccal NSAID and TA are practical to use on farm and therefore may be readily adopted by producers as options for pain relief during routine surgical husbandry procedures such as castration.

Animal Welfare

P02-002-054

The effect of pain relief at cautery disbudding on stress, behaviour, and growth rate in dairy calves and farmer perception of these methods

Nerida Evans¹, Marie Bhanugopan¹, Rafael Friere¹, Geoff Dutton¹, Jan Lievaart¹, Matthew Peterson^{2,1}¹School of Animal & Veterinary Sciences, Charles Sturt University, Wagga Wagga, ²Finley Veterinary Clinic, Finley, Australia

Objectives: 1) To assess the behavioural response of calves to cautery disbudding. 2) Assess the effectiveness of sedation, cornual nerve block and oral NSAID administration at mitigating pain, pain behaviour and stress during disbudding. 3) Assess farmer perception on calf welfare at disbudding and to assess willingness of farmers to adopt pain relief into disbudding protocols.

Materials and Methods: Healthy Holstein Friesian dairy calves (n=124) were selected from a dairy farm in the Finley region of Southern NSW. The calves were allocated to one of the following groups:

Control 1- Calves restrained in disbudding crush and 'sham' handled without disbudding being performed. Control 2: Calves sedated, cornual nerve block performed and oral NSAID administered and 'sham' handled without disbudding being performed. Treatment 1: Cautery disbudding without the provision of sedation or pain relief, Treatment 2: Cautery disbudding with the provision of pain relief (sedation, cornual nerve block and oral NSAID administration) with horn bud removal and Treatment 3: Same as treatment 2 pain relief without horn bud removal. Calves were weighed prior to the trial, 48 hours following the trial and weekly for the next 2 weeks post disbudding to assess immediate and long term changes in average daily gains. The behavioural reaction of calves to disbudding was assessed and ranked using an agitation scale (0-5). The behaviour of calves was observed for 6 hours following the procedure. Frequencies of behaviours indicative of pain such as; head shaking, ear flicking, head rubbing and foot stamping were recorded, as were behaviours considered normal in calves such as; ruminating, drinking milk and eating straw/grain. The time taken to complete each treatment was recorded to assess the time efficiency of each method. Following a demonstration of disbudding methods farmers voluntarily completed a questionnaire regarding calf welfare at disbudding and willingness to adopt pain relief protocols.

Results: There was a significant ($P \leq 0.05$) increase in average daily gain (Treatment 1= 601 g/d, Treatment 2= 666 g/d, Treatment 3 = 776.8 g/d) in dairy calves over the 2 week period post disbudding for Treatment 2 compared to Treatment 1. The provision of pain relief was also associated with a significant reduction in agitation score at the time of disbudding and calves exhibited fewer behaviours, in the 6 hours post treatment, associated with pain compared to the no pain relief group.

The results of this study show that there was significant effect on welfare and ADG in calves following disbudding procedure when sedation a local anaesthetic and an oral NSAID was incorporated into the cautery disbudding protocol.

Based on the questionnaire survey from farmers (N= 28) who observed the procedure, it was shown that 71.4% of farmers thought that pain relief at disbudding was helpful and were willing to incorporate the protocol of pain relief on their farm. Furthermore, 50% of farmers identified it as an avenue to improve the public perception of dairy farming. They agree that such methods provide a higher standard of welfare, however do hold concerns regarding the cost of such protocols.

Conclusions: It can be concluded from this study that incorporating pain relief into common husbandry procedures such as disbudding is beneficial,

both in regards to animal welfare and production. This study has also identified that producers are willing to accept and adopt these protocols to improve the welfare of their animals and also to improve the public perception of the dairy farming industry. Future studies to identify the most effective disbudding technique and investigation into avenues to reduce the cost associated with incorporating pain relief protocols into common husbandry procedures is warranted.

Consequences of Virginiamycin Used as Growth Promoter on the Prevalence of Antibiotic Resistant *E. coli* in Feces of Feedlot Cattle.

Marcio Costa¹; José A. Bessegato¹; Julio A. Lisbôa¹; Carlos H. Montemor¹; Leonardo P. Medeiros¹; Renata K. Kobayashi¹; Amauri A. Alfieri¹

¹Universidade Estadual de Londrina, Brazil, Londrina, Brazil

Objectives: This study aimed to investigate the prevalence of antibiotic resistant bacteria present in feces of feedlot cattle before and after the use of virginiamycin given as antibiotic growth promoter (AGP) and to compare treated animals with a control group.

Materials and Methods: Thirty-six crossbreed cattle (*Bos taurus taurus* x *Bos taurus indicus*) were randomly assigned to one of two groups (n=18 per group): animals treated with virginiamycin (ATB) and a control group (CON) receiving the same diet without the antibiotic. Fecal samples were collected at arrival and exit from a feedlot operation. Isolation of *Escherichia coli* was done by standard methods and 2 to 3 colonies from each plate were tested for antimicrobial resistance using the disk-diffusion method, as recommended by the Clinical and Laboratory Standards Institute guidelines. The following antimicrobial agents were selected: amoxicillin-clavulanic acid, ampicillin, aztreonam, ceftiofur, chloramphenicol, ciprofloxacin, enrofloxacin, gentamicin, nalidixic acid, streptomycin, tetracycline and trimethoprim-sulfamethoxazole. Fisher exact test was used to compare the prevalence of resistant isolates at the different sampling times and between groups (CON vs. ATB) within each moment.

Results: Two hundred six *E. coli* colonies were analyzed, of which 98 were from samples collected at arrival (CON=50 and ATB=48) and 108 collected at exit (CON=54 and ATB=54). Only 2% of isolates from arrival and 0.2% from exit showed resistance to one of the antimicrobial agent tested. At arrival, one isolate from ATB and two from CON were resistant to nalidixic acid; four from CON had intermediate resistance to amoxicillin-clavulanic acid; four from CON and one from ATB had intermediate resistance and two from CON and one from ATB were resistant to ampicillin; one from CON was resistant to enrofloxacin; six from CON had intermediate resistance to streptomycin; and two from CON and one from ATB were resistant to tetracycline. Four isolates, three collected at arrival (two from CON and one from ATB) and one at exit (CON), were resistant for both, ampicillin and tetracycline. All isolates were sensitive to aztreonam, ceftiofur, ciprofloxacin, chloramphenicol, gentamicin and trimethoprim-sulfamethoxazole.

At exit, only one isolate had intermediate resistance and one was resistant against ampicillin, and one against tetracycline (all isolated from the CON group). There was no significant difference in antimicrobial resistance between animals comparing arrival to exit, neither ATB and CON at exit ($P > 0.05$ for all the comparisons).

Conclusions: The sensitivity to several antibiotics tested in the samples collected for this study is suggestive that at these conditions, the use of virginiamycin used as AGP may not be of public health concern for the development of multidrug resistant bacteria.

Anti-Microbial Resistance

P03-003-002

Monitoring of antibiotic dispensing by veterinarians in farm animal practice in Austria

Clair L. Firth¹, Walter Obritzhauser¹, Ulrich Herzog², Reinhard Fuchs³, Klemens Fuchs³

¹Institute of Veterinary Public Health, University of Veterinary Medicine Vienna, ²Chief Veterinary Officer, Federal Ministry of Health, Vienna, ³Division for Data, Statistics and Risk Assessment, Austrian Agency for Health and Food Safety (AGES), Graz, Austria

Objectives: The Austrian Federal Ministry of Health, in common with other health authorities worldwide, is concerned about the use of antibiotics in both human and veterinary medicine. In order to be able to assess the current situation in Austria with regard to antibiotic use in food-producing animals, a new law was passed requiring veterinarians to report all antibiotics dispensed on farm. The University of Veterinary Medicine is also involved in a study as part of the ADDA (Advancement of Dairying in Austria) project, collecting data on antibiotic administration by veterinarians, with particular respect to the treatment of dairy cows with mastitis.

Materials and Methods: The Austrian "veterinary antibiotic volume flow" regulation (Veterinär-Antibiotika-Mengenströme-Verordnung) was enacted in 2014. Veterinarians treating food-producing animals are required to report all antibiotics dispensed to farmers for each calendar year. The first reports are due to cover the period 1st January 2015 - 31st December 2015. Veterinarians are required to transfer the data to the Austrian Agency for Health and Food Safety (AGES). In addition, pharmaceutical companies and wholesale pharmacies were required to provide details of antibiotics delivered to veterinarians from 2014 onwards. Furthermore, farmers can voluntarily provide details of antibiotic use and administration on farm.

Results: To date, all pharmaceutical companies/wholesale pharmacies operating in Austria have provided data on their supplies of antibiotics to veterinarians in farm practice. A total of 1733 veterinary practices are registered as having their own in-house pharmacy in Austria. Of these, 1626 ordered deliveries of antibiotics from wholesalers/pharmaceutical companies in 2014. The majority of antibiotics were supplied to a relatively small number of veterinary practices: 95% of the total volume of antibiotics ordered were delivered to just 328 practices (equivalent to 20% of the total number receiving antimicrobial products). The mean volume of critically important antimicrobials (fluoroquinolones, macrolides and 3rd-4th generation cephalosporins) made up 8% of the total volume ordered.

Cattle, sheep, goats, pigs, deer, poultry, llamas, ostriches, farmed fish, rabbits and horses are all classified as food-producing animals and veterinarians dispensing antibiotics for use in these species must report this. A number of producer organisations (such as the Poultry Association) also require their members to report antibiotic administration on farm, which goes beyond the requirements of the law.

With respect to the ADDA (antibiotic use in dairy cows) project, data collection began on 1st October 2015 and will continue until 30th September 2016. To date, 17 veterinary practices and approximately 280 dairy farms are included in this project. Data are expected to cover antibiotic administration in 7000 dairy cows (15,000 cattle in total).

Conclusions: Austrian laws regarding the dispensing of prescription-only medications by veterinarians are already much stricter than those in many other European countries. The Veterinary Medication Control law (Tierarzneimittelkontrollgesetz) precisely limits which medications can be left by veterinarians on farm. From 2016 onwards, it will be possible to analyse antimicrobial dispensing data by animal species and production method, which will provide additional insights into farm animal practice in Austria.

Anti-Microbial Resistance

P03-003-003

Multi-Drug Resistant Coagulase-Negative Staphylococci On A Single Farm In Australia

Kiro Petrovski^{1*} Manouchehr Khazandi¹ Darren Trott¹ Ricardo Aviles Ruiz² Andrew Hoare³¹The University of Adelaide, Roseworthy, Australia, ²The University of Guanajuato, Guanajuato, Mexico, ³South East Vets, Mt Gambier, Australia

Objectives: The objectives of this study were to test the antimicrobial susceptibility profiles of 37 isolates of coagulase-negative staphylococci (CoNS) from a single dairy farm in South Australia, Australia, battling a high rate of mastitis treatment failure. The testing was carried out with aims to detect the potential emerging resistance in CoNS in Australia, on a farm that heavily uses antimicrobial treatment for mastitis cases occurring in cows during lactation.

Materials and Methods: Isolates originated from 37 milk samples from cows aged 2-10 years. All samples originated from quarters that have been recently or inter currently treated for mastitis by the farm staff. The total number of submitted samples was 320 quarter-level samples from a total of 87 cows. This study concentrates on the results obtained from the 37 isolated samples of CoNS.

A pure culture of each isolate was frozen after culture from the original milk sample was stored at -80°C and used for MIC determination and confirmation of species identity by 16S rRNA sequence analysis.

Antimicrobial agents (ampicillin, cefotaxime, chloramphenicol, ciprofloxacin, gentamycin, neomycin, novobiocin, oxacillin, vancomycin, spectinomycin, streptomycin, tetracycline, and tylosin; Sigma, Australia) and antimicrobial disks (ampicillin, cefotaxime, ceftiofur, chloramphenicol, gentamycin, neomycin, novobiocin, and oxacillin; Oxoid, Australia) were obtained for determination of the minimum inhibitory concentration (MIC) of each isolate.

Minimum inhibitory concentrations (MIC) were determined using the broth microdilution technique.

From each isolate bacterial DNA was extracted by growth overnight in 5 mL Muller Hilton broth using a DNA extraction kit (Mericon DNA Bacteria Kit, Qiagen, Australia) according to the protocol recommended by the manufacturer. The extracted DNA was used for detailed identification and detection of resistance genes.

Results: A total of 37 isolates were confirmed as CoNS. The identification of these isolates found *S. xylosus* (n=9), *S. haemolyticus* (n=8), *S. succinus* (n=6), *S. fleurettii* and *S. sciuri* (n=4 of each), and *S. chromogenes*, *S. equorum*, and *S. simulans* (n=2 of each). The large proportion of the isolates obtained from these treated quarters was CoNS (28%). This should raise a question if they should be still assumed as minor or opportunistic pathogens, or it is time to discuss the need of speciation during the routine laboratory diagnostics, including their susceptibility testing.

Interestingly, despite the intercurrent or recent treatment with approved antimicrobials of all sampled quarters the number of samples yielding a pure culture was high (42.5%). The possible explanations should include too short treatment at the moment of sampling, insufficient mammary gland defence mechanisms to eliminate the pathogen after treatment and existence of resistance on the farm. In discussion with the farm staff it was found that only 4 out of 320 sampled quarters had only a single treatment and most of the 320 quarters had finished treatment in the last 12-72 hours.

A total of 19 out of the 37 CoNS (51.3%) were resistant to antimicrobials

and 14 of them (37.8%) were multi-drug resistant. In total 14/19 CoNS isolates with resistance showed oxacillin resistance.

The 37 CoNS isolates demonstrated no resistance 1, 8 demonstrated resistance to 2 antimicrobials, 5 isolates to a single antimicrobial, 3 isolates to three antimicrobials, 2 isolates to 4 antimicrobials and 1 isolate to 5 antimicrobials.

Conclusions: The results from this study indicate a relatively high prevalence of the multi-drug resistance in CoNS isolates from cases of clinical mastitis on a farm battling with mastitis treatment failure in Australia. The identification of high number of oxacillin-resistant *mecA*-negative CoNS in this study indicate the presence of particular resistance genes not completely proportional to the occurrence of the phenotypic resistance. Thus, it is opinion of the authors that combination of phenotypic and genotypic tests is essential to identify all methicillin-resistant *Staphylococcus* spp.

P03-003-004

Pharmacokinetics Of A Novel Antimicrobial Peptide In A Ruminant Model

Patrick Pithua^{1*}¹Veterinary Medicine and Surgery, University of Missouri-Columbia, Columbia, United States

Objectives: Multi-drug resistance has emerged as a significant challenge to public and veterinary medicine. Use of antibiotics in food animal production is considered a driver of such resistance. Antimicrobial peptides (AMPs) based on innate immune system cationic aromatic peptides could provide an effective alternative to traditional antibiotic use in food animal production. The aim of this pilot study was to determine the pharmacokinetic properties of the antimicrobial peptide TCMCB07 (hereafter B07) following oral, intramuscular and subcutaneous administration in preparation to assess any clinical effects in healthy post weaned dairy calves.

Materials and Methods: This study was designed to advance AMP alternatives to antibiotic use due to the failure to develop new antibiotics to combat multi-drug resistant organisms. The goal was to understand the pharmacodynamics of antimicrobial peptides *in vivo*, to prepare for experiments examining their antibacterial action in food animals, particularly ruminants. B07 was administered to 8 week old Holstein bull calves by oral, subcutaneous (SC), or intramuscular (IM) administration. Blood sampling proceeded for 24 hours after administration. After the initial sampling period, intravenous (IV) doses were given to three animals that received either SC or IM doses, and animals were sampled for another 24 hours. Reverse Phase High-Performance Liquid Chromatography (RP-HPLC) was used to measure B07 concentrations in bovine serum samples.

Results: The SC administration of 300 mg of B07 resulted in a 30 min peak of 1.68 ug/ml in blood, while the same dose given IM resulted in a peak of 1.18 ug/ml at 15 min. The SC and IM doses had similar pharmacokinetic curves. A dose of 300 mg of B07 given orally resulted in a peak blood level of 0.11 ug/ml at 24 hours. The low recovery of B07 after oral administration is likely due to extensive degradation of the peptide in the rumen. Two doses, 60 mg and 30 mg, given intravenously resulted peak levels 1 min post administration of 8.96 ug/ml and 1.55 ug/ml, respectively.

Conclusions: The absorption of B07 in circulation was optimized following parenteral administration either subcutaneously or

intramuscularly. Experiment to determine the distribution of B07 in respiratory tissue is currently underway in anticipation of its potential use for treating bovine respiratory disease.

Antimicrobial drug use and risk factors for increased treatment incidence and mortality in Swiss veal calves reared under improved welfare conditions

Matteo Lava ¹, Gertraud Schüpbach-Regula ², Adrian Steiner ¹, Mireille Meylan ¹

¹Clinic for Ruminants, Vetsuisse Faculty, ²Veterinary Public Health Institute, Vetsuisse Faculty, University of Berne, Switzerland

Objectives: The objectives of the present study were to describe and quantify antimicrobial use and to identify the major risk factors for increased antimicrobial drug use and mortality in veal farms rearing own and purchased calves in Switzerland.

Materials and Methods: A retrospective cross-sectional study was performed. Veal farms producing under a label with improved welfare standards were visited. A pretested standardized visit protocol for the farm characteristic and presence or absence of risk factors was used. Animal data such as birth date, breed, gender etc. were provided by the Swiss national animal movement database. Antimicrobial data was extracted from the farms' veterinary bills and treatment records. Antimicrobial drug treatment incidence was calculated with the defined animal daily dose methodology (TI_{ADD}). Two multivariable models were constructed, for antimicrobial drug treatment incidence (53 farms) and mortality (91 farms).

Results: Ninety-one Swiss veal farms were visited between August and December 2014. The fattening period lasted a mean of 120±28 days, mean carcass weight was 125 kg. Mean herd size was 58±12 fattened calves per year, and purchased calves were bought from a mean of 20±17 farms of origin. The mean TI_{ADD} was 21±15 daily doses per calf and year. The mean mortality risk was 4.1%, calves died at a mean age of 94±50 days, and the main causes of death were bovine respiratory disease (BRD, 50%) and gastro-intestinal disease (33%). No quarantine, shared air space for several groups of calves, and no clinical examination upon arrival at the farm were associated with increased TI_{ADD}. Maximal group size and weight differences >100 kg within a group were associated with increased mortality risk, while vaccination and beef breed were associated with decreased mortality risk. Most antimicrobial treatments (84.6%) were given as group therapy with oral powder fed through an automatic milk feeding system. Combination products containing chlortetracycline with tylosin and sulfadimidine or with spiramycin were used for 54.9%, and amoxicillin for 43.7% of the oral group treatments. The main indication for individual treatment was BRD (73% of the cases). The mean age at the time of treatment was 51 days. Individual treatments were applied through injections in 88.5% of the cases: fluoroquinolones were administration in 38.3%, penicillins in 25.6%, macrolides in 13.1%, tetracyclines in 12.0%, 3rd and 4th generation cephalosporins in 4.7%, and florfenicol in 3.9% of the cases.

Conclusions: The present study allowed for identifying the main risk factors for increased antimicrobial drug use and mortality. This is an important basis for future studies aimed at reducing treatment intensity and mortality in veal farms. These results indicate that improvement is needed in the selection of drugs for the treatment of veal calves according to the principles of prudent use of antibiotics.

P03-003-006

The dynamics of calves intestinal colonization Extended-spectrum b-lactamase (ESBL)-producing Escherichia coli in terms of dairy farms.

Jana Smidkova ¹, Alois Cizek ¹

¹University of Veterinary and Pharmaceutical Sciences Brno., Brno, Czech Republic

Objectives: In the last decade antimicrobial resistance monitoring studies have documented rise in the prevalence of resistance to extended-spectrum cephalosporins (ESCs). Resistance to ESCs is often caused by a group of enzymes called extended-spectrum beta (β)-lactamases (ESBLs) and/ or plasmid-mediated AmpC (pAmpC) β – lactamases. In this study we focused on collecting faecal samples from calves since birth to 40 days old.

Materials and Methods: Since birth we were collecting faecal swab and fecal samples. Also swabs from farm environment were taken. Rectal swabs and fecal samples were inoculated directly on MacConkey agar (Oxoid, GB) supplemented with 2 mg/l cefotaxime (Sigma, CR) and incubated 24 hours at 37°C. The fecal, environmental samples (surface smears, in-line milk filters), water, feed (colostrum, milk) and bedding samples were cultured as above with additional pre-enrichment step in MacConkey broth (Oxoid, UK). Simultaneously, the CREC isolates were subjected to antibiotic susceptibility testing by disk diffusion method on Mueller-Hinton agar (Oxoid) in accordance with CLSI (2013a,b) using 12 antibacterial substances: amoxicillin-clavulanic acid (AMC, 30 mg), ampicillin (AMP, 10 mg), cephalothin (KF, 30 mg), ceftazidim (CAZ, 30 mg), chloramphenicol (C, 30 mg), ciprofloxacin (CIP, 5 mg), gentamicin (GN, 10 mg), nalidixic acid (NA, 30 mg), streptomycin (S, 10 mg), trimethoprim-sulfamethoxazole (SXT, 25 mg), sulfonamides compounds (S3, 300 mg), and tetracycline (TE, 30 mg) (Oxoid, UK).

Results: Ninety-six faecal samples were collected from 12 calves 1 to 40 days of age. After cultivation on McConkey agar plates containing cefotaxime (2 mg/litre) cefotaxime-resistant and lactose-positive colonies were counted. The largest increase of colonies was during the third and the seventh day of life. Noticeable drop in AmpCPEC density or its discontinued shedding were recorded in the end of investigated period. All fecal samples from mother-cows, water supply, feed of calves (colostrum, milk, milking parlor) and bedding samples were negative. Positive samples were found on in-line milk filters.

Conclusions: AmpC-producing E. coli (AmpCPEC) were detected in faeces of all 12 calves. Shedding density of AmpC-producing E. coli has highest concentration 8.0 log₁₀ CFU/gram. It has increasing trend first week of life, than between first and second week the concentration established and downward trend was recorded after the third week of life.

Comments: The paper is based on the IGA VFU Brno project

Enrofloxacin resistance monitoring: Antimicrobial susceptibility of bovine respiratory pathogens in Germany

Carolin Ludwig ¹, Stefan Fälker ¹, Gert Daube ¹, Sonja-Maria Tennagels ¹, Anno de Jong ¹, Bernd Stephan ¹

¹Bayer Animal Health GmbH, Leverkusen, Germany

Objectives: Antimicrobial resistance is a concern in the antimicrobial therapy of both humans and animals. Knowledge on the actual susceptibility and its development over the years is important for ensuring long-term antimicrobial efficacy. Therefore, in the early nineties of the past century Bayer has established a susceptibility monitoring program for target animal pathogens collected from food-producing animals in Germany. Here, the susceptibility status for enrofloxacin (the active ingredient of Baytril®) is presented with regard to bovine pathogens recovered from respiratory tract samples.

Materials and Methods: Samples from diseased animals were collected across Germany between 2006 and 2015. Per farm and outbreak only one isolate was included. The Minimum Inhibitory Concentrations (MICs) of enrofloxacin were determined by agar dilution methodology according to the Clinical and Laboratory Standards Institute (CLSI; VET01-A4, 2013 and previous versions). MIC range, MIC₅₀ (≥5 isolates/species) and MIC₉₀ (≥10 isolates/species) were determined. Enrofloxacin resistance was calculated using the CLSI clinical breakpoint of ≥2 µg/mL for *Mannheimia haemolytica*, *Pasteurella multocida* and *Histophilus somni* (VET01-S, 2015).

Results: In total, 216 isolates were tested. The most common species isolated from respiratory tract samples were *P. multocida* (n=97) and *M. haemolytica* (n=57). In addition, other species were found in lower numbers, e.g. *Pseudomonas aeruginosa* (n=20), *Trueperella pyogenes* (n=15), *Klebsiella* spp. (n=8), and *H. somni* (n=5). MIC₅₀ and where applicable MIC₉₀ values were 0.008/0.015 for *P. multocida*, 0.03/0.5 for *M. haemolytica*, 1/2 for *P. aeruginosa*, 1/8 for *T. pyogenes*, 0.006/NA for *Klebsiella* spp. and 0.03/NA for *H. somni*. For *P. aeruginosa*, *T. pyogenes* and *Klebsiella* spp. resistance rates could not be determined due to the lack of a clinical breakpoint. For *P. multocida*, *M. haemolytica* and *H. somni* no resistant isolates were found.

Conclusions: This survey demonstrates a very high susceptibility of respiratory pathogens obtained from German cattle to enrofloxacin even after more than two decades of therapeutic use of fluoroquinolones in veterinary medicine. Fluoroquinolone resistance was absent for *M. haemolytica*, *P. multocida* and *H. somni* during the past 10 years. Results are consistent with findings of other national and European monitoring surveys such as GERM-Vet (2012, 2015) and VetPath (El Garch et al., 2015). In spite of this high susceptibility, prudent and responsible use of fluoroquinolones as well as resistance monitoring are imperative.

Understanding current practice in the use of antimicrobials in livestock farming and informing interventions to reduce antimicrobial resistance

Henry J. Buller¹ Steven J. Hinchliffe¹ Joanna S. Hockenhull¹ Kristen K. Reyher² Andrew Butterworth² Cheryl A. Heath² David C. Barrett^{2*}

¹College of Life and Environmental Sciences, University of Exeter, Exeter, ²School of Veterinary Sciences, University of Bristol, Bristol, United Kingdom

Objectives: This research sought to:

- provide evidence-based analysis of how and why antimicrobials (AMs) are prescribed and used in livestock systems,
- explore the extent to which farmers, veterinarians and key actors are aware of the issue of antimicrobial resistance (AMR),
- identify how awareness becomes embedded in and through social

positions and social practice,

- inform future AM interventions in the livestock sector.

Current AM uses in livestock were investigated, focusing upon the interfaces between farming, food production, veterinary and advisory practices as a basis for understanding how changes to these practices might be achieved.

Materials and Methods: A combination of three different yet inter-linked methodological approaches were used:

- A Rapid Evidence Assessment (REA) was undertaken, drawing upon an initial database search of over 4,500 published and unpublished works, narrowed down to 31 papers from which a detailed comparative assessment was generated. The REA also served to contextualise the subsequent empirical research.
- A Q-sort and analysis was developed as a means to interrogate view points and value positions with respect to AM use and related issues (such as animal welfare, public health and governance).
- Qualitative, semi-structured interviews with selected farmers, veterinarians and key actors across the poultry, pig and dairy livestock sectors were undertaken. For each sector, five farmers (at least one of which in each sector was organic) and three vets were interviewed (on farm or in practice). Additionally, interviews were held with a number of key actors from the professional bodies, the food sector and assurance/certification bodies. In total, 32 individual interviews were undertaken. The transcribed interviews were subsequently analysed for common and contradictory themes, for specific examples of practice, for relevant statements that would support identified common positions and for an understanding of the range of practices within which the use and prescription of AMs constituted a regular (or irregular) component.

The REA, Q-sort and qualitative research were then brought together to draw up a series of specific policy-informing messages.

Results: Four evidence categories emerged from the REA: on the volumes/dosage and application of AMs in farming systems, on vet prescription practice in different countries, on farmer attitudes towards AM use and on questions of data and recording of AM use.

The Q-sort suggested there were significant shared values as well as differences across the livestock sectors and across personnel and professions. Shared positions included a relative disdain for the risks posed by farming to AMR in the wider environment and a tendency to underplay the importance of the livestock sector's contribution to AMR as a human health issue. There were three broad positions that vets and farmers tended to take:

- The Modern Business approach - antibiotics are already being phased out through modern farming methods which prioritise hygiene, health planning and herd management; AM use is already appropriate and under control.
- The Interventionist - changes in AM use can be brought about through better farmer education and a veterinary-led understanding of the issue. This position is most amenable to making changes in AM use in livestock.
- The Autonomist - there is a fear that over-zealous regulation or outside influence will lead to inappropriate restrictions and further erode the viability of farming.

These responses suggest the best hope for behavioural change towards more appropriate use is to work with farmers and vets rather than regulate in a top-down fashion.

The qualitative research, by focusing on key actors and allowing them to drive the discussion, enabled deeper insight into these positions.

Conclusions: AMs are seen as a tool in maintaining health of farm

animals - the key issue is their inappropriate use. Principal areas of concern:

- prophylactic and metaphylactic use
- use to treat conditions not caused by sensitive microorganisms
- unnecessary use of later generation AMs
- over-dependence on medicines as a replacement for health management, and
- incorrect dosage

Targeting these areas is a priority, though achieving change requires more than awareness. Changes can be both facilitated and constrained by existing social and practical relationships. Governance of AMs will require a mixture of regulation and responsible action by the industry.

A Survey of Anti-microbial Resistance in Organisms Recovered from Sand, Sawdust and Recycled Manure Solids after Use as Dairy Cow Bedding

Andrew Bradley^{1,2}; Katharine Leach¹; Ian Ohnstad³; Martin Green²; Victoria Prout¹; Caroline Hunt¹; Barbara Payne¹

¹Quality Milk Management Services Ltd, Wells, ²School of Veterinary Medicine and Science, University of Nottingham, Loughborough, ³The Dairy Group, Taunton, United Kingdom

Objectives: One concern surrounding the use of recycled manure solids as bedding is that the potential for the closed loop offered by this process may be conducive to the persistence and perpetuation of anti-microbial resistance (AMR) (Bradley et al., 2014). The aim of this study was to establish a 'baseline' level of AMR data and isolates from farms bedding on different materials for the purposes of initial and future comparison.

Materials and Methods: The coliforms and *Enterococcus* spp were selected as organisms likely to be representative of environmental organisms with a known ability to harbour and transfer antimicrobial resistance. Six of each of the selected pathogens were collected from bulk milk (3) and bedding (3) samples from 125 farms using sand, sawdust or RMS as bedding materials. Data on antibiotic use in adult dairy cattle alongside other pertinent management information was collated from questionnaires completed during the farm visits which were conducted as part of a larger survey of bedding use and animal health in the UK.

Antimicrobial sensitivities were determined using a VITEK® 2 (Biomerieux; Basingstoke UK) following the recommended protocols. For the purposes of analysis, minimum inhibitory concentrations (MICs) of each antimicrobial for each organism were ranked and differences analysed using a non-parametric approach. Where univariable analysis identified differences in MIC between bedding types, multivariable analysis was also conducted using conventional models. These models took into account a number of different farm variables and management factors, these included (amongst others) class and route of antibiotic use, geographic location of the farm, organism 'group', housing variables as well as aspects of RMS use.

Results: A total of 724 coliforms and 793 *Enterococcus* spp were collated from 125 farms. Univariable analysis identified significant differences in the MICs of coliforms between the different bedding types for ampicillin (p=0.009), amikacin (p=0.028), chloramphenicol (p=0.049), ceftiofur (p<0.001), cephalixin (p=0.010), enrofloxacin (p=0.003),

nitrofurantoin (p=0.053) and piperacillin (p=0.004). Multivariable analysis confirmed that the difference in MICs between bedding groups could be explained by the farm variables recorded, for ampicillin, nitrofurantoin and piperacillin. Differences were confirmed amongst the other antimicrobials tested. MICs were significantly higher for amikacin for coliforms from farms bedded on RMS compared to sand or sawdust and significantly lower for chloramphenicol for coliforms from farms bedded on RMS compared to sand or sawdust. MICs were significantly higher for enrofloxacin for coliforms from farms bedded on sand compared to RMS or sawdust and significantly lower for ceftiofur and cephalixin for coliforms from farms bedded on sand compared to RMS or sawdust.

Univariable analysis identified significant differences in the MICs of *Enterococcus* spp between the different bedding types for clindamycin (p<0.001) and enrofloxacin (p=0.013); these were confirmed by multivariable analysis. MICs for clindamycin were significantly higher for *Enterococcus* spp recovered from farms bedded on RMS compared to sand or sawdust. MICs for enrofloxacin were significantly higher for *Enterococcus* spp recovered from farms bedded on sawdust compared to RMS or sand.

Conclusions: This study has not generated any clear evidence that the short term use of recycled manure solids as bedding, as compared to sawdust and sand, is associated with a general increase in MICs of the major classes of antibiotics when considering coliforms and *Enterococcus* spp. Further research, using the dataset generated by this study and elsewhere, is needed to further our understanding of any potential interactions between bedding type and management and antimicrobial resistance in the environment.

A Benchmarking Review Of Antibiotic Use In New Zealand From 2005 To 2014

Mark Bryan¹; Eric Hillerton²; Steve Merchant³; Dennis Scott⁴; Callum Irvine⁵

¹Head of R&D, VetSouth Ltd, Southland, ²Consultant, NZVA, Cambridge, ³MD, Pet Doctors, Auckland, ⁴AMRSG, ⁵HOVS, NZVA, Wellington, New Zealand

Objectives: Antimicrobial resistance is widely considered a significant global threat to the health of humans and animals, and the very future of antibiotics in successful animal and human health management is at risk. The New Zealand Veterinary Association has released an aspirational statement that 'by 2030, NZ Inc will not need antibiotics for the maintenance of the health and welfare of animals'. In the context of that goal, it is necessary to determine the current level of antibiotic use in New Zealand. This is the first assessment of antimicrobial use (using sales as a proxy) by population corrected unit (PCU) at a national level in New Zealand.

Materials and Methods: National antimicrobial sales data were available for the past 10 years. Animal population data was available from agricultural censuses, with the exception of wildlife, feral species and minor species such as llamas, alpacas, etc). The total biomass in New Zealand of each species was calculated using accepted industry estimates of bodyweight and age distribution, and the level of antibiotic use was determined based on population corrected units (PCU). Comparative data were compiled from other countries (where available) to enable a comparison between countries of use levels. Finally, these data were compared to the data similarly obtained on the use of antimicrobials in humans in New Zealand.

Results: There has been a slight increase in antimicrobial sales of approximately 2.5%/year or 1.5 t/year over the past 10 years, mostly in the past five years. This was despite a gradual reduction in animal biomass of approximately 4% over that time period. The dairy industry contributed the greatest proportion of biomass to the country total. In comparison with 29 other developed countries, using data for 2012 the last year available, New Zealand was the third lowest user (9.4 mg ai/PCU) of antibiotics in animals. However, this rate of use, which has some annual fluctuations, has increased by approximately 25%. Analysis shows that usage of antibiotics for human health in New Zealand is significantly greater (x12) than for animals although the human use is close to the international average.

Conclusions: This is the first report of baseline data with which the New Zealand animal health industry, especially veterinarians as regulated prescribers, can develop and measure success in maximising the life of antibiotics for animal health and welfare.

In particular, by allowing comparison with international data, these data allow the veterinary profession to move forward on its aspirational goal with a clear understanding of the current position.

Molecular Investigation and Antimicrobial Susceptibility of *Staphylococcus aureus* in Mastitic Cholistani Cattle

Riaz Hussain¹ Abdul Qayyum¹ Jawaria A. Khan² Muhammad Avais² Nisar Avais¹

¹University College of Veterinary & Animal Sciences, The Islamia University of Bahawalpur, Bahawalpur, ²Department of Clinical Medicine and Surgery, University of Veterinary and Animal Sciences, Lahore, Pakistan

Objectives: Sub clinical mastitis primarily with microbial etiology is amenable to different antibiotic therapy and the outcome is doubtful due to association of a variety of microorganisms, host-specificity and continual evolution of different antibiotic resistant strains of microorganisms. Therefore, the present study was ascertained to investigate the presence, genotypic characteristics of *Staphylococcus aureus* isolates recovered from subclinically mastitic cholistani cattle and the effectiveness of different antibiotics against these pathogens by disc diffusion technique

Materials and Methods: For this purpose milk samples were collected from a total of 1457 lactating cholistani cattle and screened for mastitis using California Mastitis Test. Lactating Cholistani cows through cluster sampling were included from 71 villages and 27 tobas of Cholistan in this study. All the positive samples were processed for culturing

of *Staphylococcus aureus* isolates. *Staphylococcus aureus* isolates were identified on the basis of colony characteristics, coagulase test, biochemical features and amplification of *spa* (*spa-X*) and coagulase (*coa*) genes.

Results: The results of PCR revealed that amplification of *spa* (*spa-X*) gene yielded different PCR products (400bp and 350bp) while coagulase (*coa*) produced different products size (390bp, 500bp and 600bp) indicating genetic variation within and among different herds of the cattle. Moreover, results of this study showed that the *spa* (*spa-X*) gene present in coagulase positive (179) and coagulase negative (4) *S. aureus* isolates. *S. aureus* isolates were fully sensitive (88%) to amoxicillin, followed by enrofloxacin (78%) and highly resistant to penicillin (65%) and cephadrine (100%)

Conclusions: It is therefore concluded that *S. aureus* isolates were genetically different in the study areas and among the different herds of the animals. In addition the results of this study indicated that the amoxicillin is drug of choice for treating subclinical mastitis.

Bacterial Etiology Of Clinical And Subclinical Mastitis In Indigenous Goats And Multiple Drug Resistance Of The Isolates

Lubanza Ngoma¹ Mulunda N. Mwanza¹

¹Animal Health, North west University, Mafikeng, South Africa

Objectives: Due to the aforementioned economic and sanitary problems, the research will be to isolate and identify the pathogens that are causing intramammary infection in small ruminants in herds in communal areas of Mafikeng. Following identification, the pathogens will be evaluated for their antibiotics susceptibility profile to suggest suitable antibiotic treatment

Materials and Methods: Isolates were Gram stained using standard techniques, which differentiates bacterial species into Gram positive and Gram negative (Cruikshank et al., 1975). A number of classical phenotypic tests were performed using BioMérieux API 20E system. The total genomic DNA of cultivated isolates was purified following Zymo-Research Fungal/Bacterial DNA kit instructions. The concentrations of purification of DNA were assessed using a nanodrop (Bio-Rad, South Africa). Amplification of 16S rDNA gene was carried out in reaction volume of 50 µL. Two sets of primers were used: forward 27F (5'-AGA GTT TGA TCC TGG CTC AG-3') and reverse 1492R (5'-TGA CTG ACT GAG GCT ACC TG-3'). Amplified fragments of DNA were resolved in 1% w/v agarose gel and visualized using Gel Doc TM XR+ with image Lab TM software (Bio-Rad, South Africa) to confirm the expected size of the product. The isolates sequences will be subjected to BLAST searches to verify identity, taxonomic classification based on sequence similarity measures, and phylogenetic interpretation. Five antibiotic discs (Oxoid) were used: Gentamicin (10 µg), Streptomycin (10 µg), amoxicillin (5 µg), Ciprofloxacin (5 µg) and Ampicillin (10 µg). The tests were performed according to the guidelines of the Clinical Laboratory Standards Institute (Bauer et al., 1996)

Results: A total of 1000 raw milk samples from goats were analyzed. Samples were obtained from different collecting points from Mafikeng town; North-South. The prevalence of clinical mastitis was found significantly ($p < 0.01$) higher in South (H = 47; 79.66%) in comparison to the North (H = 12; 20.34%). Bacteriological analysis showed that South

had 94.44% of bacterial infection compare to North 15%. No significant differences was observed on the status of bacterial pathogens between clinically (H = 55; 93.22%) and sub-clinically (H = 47; 95.92%) of both areas. The major bacterial isolated were Staphylococcus spp. (38.98%), Escherichia coli (27.12%) and Bacillus spp. (10.17%). Antibiotic susceptibility results showed a relatively high level of resistance to ampicillin, amoxicillin and streptomycin, whereas gentamicin and ciprofloxacin were found to be the most effective drugs

Conclusions: These results indicate the high prevalence of mastitis in apparently normal quarters of lactating goats and therefore, there is a need for the prudent use of antibacterial in animal health and production through bacteriological and antibiogram studies and therefore, there is a need for the prudent use of antibacterial in animal health and production through bacteriological and antibiogram studies in mafikeng (South Africa).

Anti-Microbial Resistance

P03-003-013

Assessing the prevalence of ESBL Escherichia coli and antimicrobial resistance of E. coli isolates in cattle faeces on farms in N. Somerset, England.

Andrea E. Turner¹*Kristen K. Rayher¹Tristan Cogan¹Matthew Avison²Katy Turner³David C. Barrett¹

¹School of Veterinary Sciences, ²School of Cellular & Molecular Medicine, ³School of Social & Community Medicine & School of Veterinary Sciences, University of Bristol, Bristol, United Kingdom

Objectives: The first aim of this project was to ascertain the prevalence of antimicrobial resistance (AMR) including multidrug and extended-spectrum beta lactamase (ESBL) resistance in E.coli isolates(i.e. the proportion of E. coli isolates showing resistance to one or more antimicrobial). These isolates were from adult dairy cattle faecal samples on North Somerset farms, England, which have reduced their use of critically important antimicrobials over the last five years.

The second aim was to examine the correlation between the amount and type of antibiotics used on these farms and the prevalence of antimicrobial resistance AMR in E. coli isolates.

Materials and Methods: Cattle were enrolled prospectively on seven conventional dairy herds in North Somerset which varied in size between 100 and 200 milking cows. Faecal samples were collected from rectal gloves after palpation of cows presented to veterinary surgeons for fertility examinations. Information about animal numbers and management practices was collected for risk factor analysis. Kirby-Bauer antibiograms were performed for each isolate (bsac.org.uk). These antibiograms were designed to look for patterns of resistance associated with plasmids that also carry ESBL resistance, as well as representing the antimicrobial groups commonly used on farms. Resistant isolates (those showing resistance to one or more antimicrobial) were stored for future pulsotyping, and all faecal samples were stored for use in future research.

Medicine audits, performed using medicine sales records from the University Farm Animal Veterinary Practice for the previous four years, were available for all farms. These audits were used to assess the antimicrobial use on each farm. Medicine sales records were also used to calculate animal daily doses of each group of antimicrobials prescribed and supplied to each farm.

Correlation between antimicrobial use and the presence of AMR, including ESBL, and risk factors for AMR are being assessed using

logistic regression, and the presence of resistant isolates will be analysed with respect to antimicrobial usage on each individual farm over the previous four years.

Results: Preliminary results are presented as only half (approximately 700) isolates have so far been processed and are available for analysis. These initial isolates show the highest levels of resistance to amoxicillin (mean 86%, range 79–96%), streptomycin (mean 29%, range 0–58%) and amoxicillin-clavulanate (mean 5%, range 0-9%). Resistance was present on at least one of the seven farms for every antibiotic group tested, other than the carbapenems (imipenem).

Multidrug resistance (resistance to 3 or more antimicrobials) was found on all seven of the farms. The mean prevalence of multidrug resistance was 6.7% (6.5 isolates), with a range from 2–9% (1-15 isolates) between farms. Multidrug resistant isolates are primarily resistant to many, if not all, of the following antimicrobials: streptomycin, amoxicillin and amoxicillin-clavulanate.

Resistance to extended-spectrum (3rd and 4th generation) cephalosporins was found on four of the seven farms. Resistance to fluoroquinolones was also found on four of the seven farms, but only one farm had resistance to both fluoroquinolones and extended-spectrum cephalosporins together. Interestingly, this farm had only reduced its use of protected antimicrobials 18 months before the study began, and therefore had used these classes of antimicrobials most recently compared to the other farms.

ESBL E.coli isolates were found on three of the seven farms at prevalences of 0.6 – 2.7% (1 - 4 isolates).

Conclusions: The preliminary results of this study suggest that a wide variety of resistance mechanisms are present in faecal E. coli from cattle on farms in North Somerset, and that up to 9% of isolates on individual farms, are multi-resistant.

ESBL E.coli isolates have also been found on three of the seven farms, confirming that dairy cattle are a reservoir of ESBL isolates in North Somerset. The prevalence of ESBL E.coli thus far is lower than has been reported in at least one other study performed on a UK dairy (Watson et al., 2012).

Comments: Further analysis is underway regarding association and correlations between antimicrobial use on the farms and AMR, as well as risk factors for AMR. These analyses should be available for presentation by WBC in July 2016.

Isolation And Characterization Of The Antibacterial Effect Of Bacteriophages Specific For Shiga-Toxic Esherichia Coli Strains Isolated From Calves

Mohammed Alomari^{1,2}*Renata Urban-Chmiel²Marta Dec²Anna Dudzic²Andrzej Puchalski²Andrzej Wernicki²

¹Department of Preventive Medicine. Faculty of Veterinary Medicine., University of Al Muthanna, Al Diwaneyah, Iraq, ²Institute of Biological

Bases of Animal Diseases. Faculty of Veterinary Medicine, University of live science in lublin, Lublin, Poland

Objectives: The growing phenomenon among many bacterial antibiotic resistance and the associated difficulty in effectively eliminate infections contribute to the development of alternative methods for the elimination of pathogens, such as, a phage therapies. Based on these, the aim of the study was the isolation and estimation of antibacterial activity of chosen bacteriophages specific for Shiga positive *Escherichia coli* strains isolated from calves in In vitro conditions.

Materials and Methods: The material consisted of 20 Shiga positive (STEC) of *E.coli* strains isolated from calves. The 12 *E. coli* strains were obtained from the National Veterinary Research Institute in Pulawy (Department of Hygiene of Food of Animal Origin) and the 9 strains were coming from own collection and were isolated from calves with clinical signs of diarrhea in Lublin's region.

Isolation of bacteriophages was carried out from sewage obtained from cattle housing systems according to Huff et al. (2002). Bacteriophage morphology was examined using a transmission electron microscope by negative-stained prepare with 2% silicotungstate (Xie et al. 2005). The range of lytic activity against Shiga-toxic strains of *E. coli* was determined by plaque assay on double top agar plates according to Huff et al. (2002). The lytic titres evaluated by the dilution method in SM buffer according to Golec et al. (2011).

The genetic material from the obtained bacteriophages has been isolated according to the protocol of phage DNA Isolation Kit (NORGEN, Ca). The restriction analysis of the obtained material has been carried out with using of restriction enzymes Hind III, ClaI and XbaI with (Fermentas, Lithuania). The procedure of restriction analysis has been carried out according to the producers's instruction.

Results: Overall, the present study were obtained 8 bacteriophages that based on morphological qualified for two families, five of their belong to Myoviridae and three to Siphoviridae. The lytic titres evaluated by the dilution method in SM buffer were ranged from 5×10^5 pfu/ml to 4×10^{10} pfu/ml add unit. The obtained in the restriction analysis profiles showed a similar restriction fragments ranged from 405.14bp to 4659.75 bp. The obtained results showed that the examined phages specific to ETEC strains isolated from calves. Those phages had complete lysis on *E.coli* strains on double-layer agar plates, and showed an antibacterial activity against 12 examined *E. coli* strains. This result confirms the antibacterial activity of the obtained bacteriophages and is beneficial for using of bacteriophages in elimination of *E. coli* infections in cattle.

Conclusions: To sum up, it can be said that the obtained phages exhibit antibacterial activity against to examined ETEC strains isolated from calves. The obtained results allow for further research in order to increase their use of targeted therapies in calves with symptoms of diarrhea caused by *E. coli*.

Successful treatment of a multi-drug resistant *Pseudomonas aeruginosa* infection following a digit amputation in a Belgian Blue calf.

Martin Tomlinson¹, James P. Crilly¹, Alexander Corbishley¹, Andrew Hopker¹

¹Farm Animal Practice, Royal (Dick) School of Veterinary Studies, Edinburgh, United Kingdom

Objectives: Digit amputation is a commonly performed surgery in the bovine patient. Whilst it is most commonly performed for infections of the deep structures of the foot, here we describe its application to resolve a chronic proximal interphalangeal septic arthritis.

Materials and Methods: An 8 month-old Belgian Blue calf presented to the Royal (Dick) School of Veterinary Studies with a month long history of right forelimb lameness. The owner of the animal had instigated treatment (without veterinary consultation) with daily intramuscular penicillin & dihydrostreptomycin, which he continued for 1 month without any improvement in the degree of lameness. Radiography revealed complete destruction of the medial proximal interphalangeal joint (PIPj) with lysis and bony proliferation of the proximal aspect of the proximal phalanx (P1). Due to the location, chronicity and severity of the infection, digit amputation by a high approach was indicated.

Upon lack of clinical improvement the pastern was again radiographed and radiographic findings used to guide further curettage of any devitalised tissue. The wound was swabbed for bacteriological culture and sensitivity due to the poor rate of healing, the infected appearance of the developing granulation tissue and the unpleasant smell and greenish discharge associated with the wound.

Results: Multi-drug resistant *Pseudomonas aeruginosa* infection was subsequently diagnosed as the cause of poor healing of the surgical wound.

Antibiotic administration was therefore discontinued and the treatment regime changed to focus on topical wound management. The wound was lavaged daily with 3% Hydrogen Peroxide applied under pressure using a 30ml syringe and 16 gauge needle. Ordinary table honey was applied with a clean dressing daily. This was continued for one week, after which time the wound bed was filled with healthy granulation tissue, only normal physiological discharge was seen on wound dressings and the degree of lameness was markedly improved. Wound dressing was then halted. The wound was covered in silver sulphadiazine cream and left open. The animal was discharged 3 days later.

Conclusions: This case report highlights the benefits of targeted diagnostics (radiography and bacterial culture and sensitivity) in the treatment of refractory or complex orthopaedic cases in cattle and the use of non-pharmacological therapies (hydrogen peroxide and honey dressings) in the treatment of antibiotic resistant pathogens.

Comments:

- Diagnostic imaging can be a useful tool in guiding decision making in orthopaedic procedures in cattle.
- Culture and sensitivity of causative organisms should always be considered as part of responsible use of antimicrobials, particularly when poor treatment responses occur.
- Alternative therapies and wound care can produce excellent results.
- A considered approach to diagnostics and case management are vital to maintain animal welfare and minimise economic losses.

How good management practices reduce the curative antibiotic use in cattle: the example of subclinical ketosisDidier Raboisson¹, Maxime Barbier²¹INP-ENVT INRA-IHAP, ²INP-ENVT, Toulouse, France

Objectives: Good herd management is known to mitigate antimicrobial use, but few to no quantification of such a relationship is available. Subclinical ketosis (SCK) promotes the occurrence of infectious diseases which require antibiotics for curative treatment. The control of SCK is based on peripartum management and/or use of preventive monensin bolus (Kexxtone®) for cows at risk for SCK. The objective is to quantify the decrease in curative antibiotic use (i) when farmers reduce the prevalence of cows at risk for SCK or (ii) when they use the bolus Kexxtone® to prevent SCK in cows at risk for SCK.

Materials and Methods: A stochastic model was built to calculate the total quantity of curative antibiotics at the herd level for various prevalences of cows at risk for SCK. Scenarios with or without Kexxtone® to prevent SCK (with fear or good targeting of cows) were done. The prevalence of SCK was determined for (i) the various prevalence of cows at risk for SCK and (ii) using or not Kexxtone® on cows at risk. The total quantity of curative antibiotics used is calculated thanks to the prevalence of SCK and to the odd-ratio of diseases in case of SCK compared to no SCK. Most of these diseases were considered treated with antibiotics, as commonly seen on the field.

Most popular scenarios included: prevalence of cows at risk for SCK between 10 and 80 percent; efficacy of monensin to prevent SCK fixed at 0.45, 0.66 and 0.85; OR for cows at risk for SCK to really have SCK fixed at 2.2 or 4.5. Calibrations were provided by literature review, meta-analysis and expert opinion.

Results: First, the association between the decrease in prevalence of cows at risk for SCK and the decrease in the quantity of curative antibiotics varied between situations. The decrease in the quantity of curative antibiotics started from few percent for low decrease in cows at risk for SCK, but reached 10 to 25 percent in the most popular scenarios (with calibration taken on the average of ranges). For instance, the decrease in the prevalence of cows at risk for SCK from 80 to 10 percent, corresponding to a decrease of SCK prevalence from 68 to 17 percent, led to a decrease in the quantity of curative antibiotics by 25 percent. The relationship was linear. With the extreme calibration, the decrease in quantity of curative antibiotics achieved 35 percent. Whatever the calibration, the low decrease in the quantity of curative antibiotics compared to the decrease in SCK prevalence was in agreement with the base level of curative antibiotics use in cows without SCK.

Second, using monensin with very good to good accuracy (perfect targeting or 80 percent of cows well targeted, respectively) allowed a decrease up to 20-25 percent in the quantity of curative antibiotics when the prevalence of cows at risk for SCK was high. The decrease in quantity of antibiotics allowed when the prevalence of cows at risk for SCK was moderate is from few percent up to 10-15 percent. Results showed that the quantity of curative antibiotics was stabilized at the level observed for low prevalence of cows at risk for SCK, when this prevalence was high and the monensin bolus was used.

Conclusions: The results showed that good management practices such as SCK control thanks to peripartum management (without Kexxtone®) were a powerful way to reduce the curative antibiotic use. The results are of great interest when compared to the 25 percent decrease objective provided by French policy-makers (EcoAntibio program).

Using Kexxtone® is also a powerful tool to stabilize the curative use of antibiotics when the prevalence of cows at risk for SCK is increasing. When Kexxtone® is used, the hazard regarding antimicrobial resistance that is linked to either the use of monensin or curative antibiotics (such as cephalosporin) has now to be assessed.

Anti-Microbial Resistance

P03-003-017

Methods used in a Flemish campaign to create awareness on responsible antimicrobial use in the veal industryJozefien Callens¹, Bart Pardon², Isabelle Degezelle³, Stefaan Ribbens⁴, Koen De Bleecker⁴¹Animal Health Service Flanders, Torhout, ²Department of Large Animal Internal Medicine, Faculty of Veterinary Medicine, Ghent University, Merelbeke, ³Agro- and biotechnology, Vives, Roeselare, ⁴Animal Health Service Flanders, Drongen, Belgium

Objectives: Antimicrobial consumption in Belgian livestock is among the highest of Europe, and this is translated in high levels of antimicrobial resistance in commensal, zoonotic and pathogenic bacteria. Especially in pigs, poultry and veal calves antimicrobial use is intensive. The Flemish government funded a project (the responsible use of antibiotics in intensive reared livestock) with the objective to create awareness in farmers and veterinarians. The objective of this abstract is to describe the topics communicated, and the ways of communication, used to create awareness about antimicrobial use and resistance in the veal industry.

Materials and Methods: An expert panel consisting of academic staff (n= 3), veterinarians of the animal health service (n=2) and veterinarians active in the veal industry (n=5) was constructed and guided by the Flemish advice organ on veterinary antimicrobial use (AMCRA). Available information on administration ways and indications for antimicrobial use in the veal industry was inspected, and possibilities to reduce were listed. Next, actions to reduce antimicrobial were priority ranked according to their possible contribution to antimicrobial reduction, the likeliness to be implemented at short term and the ratio labor/achieved reduction. Subsequently, the campaign was focused on the top 5 action points. At every stage, outcomes were communicated with the persons involved in the same exercise for pigs and poultry.

Results: Ranking according to the expert panel was as follows: (1) avoiding routine antimicrobial group treatments, (2) avoiding two or more antimicrobials in one treatment, (3) calf quality control at arrival, (4) stable ventilation adjustment, (5) correct dosing of antimicrobials, (6) avoiding oral antimicrobial use, (7) avoiding group treatments and (8) vaccination upon arrival. The first two measures were at the veterinarians discretion and had already been markedly adjusted. The third measure, calf quality control at arrival, could only be influenced by the integrators and not by the farmers directly. Parameters for selection (immunoglobulin levels at arrival, a bodyweight over 50 kg at arrival, no persistent infection with bovine viral diarrhoea virus and no diarrhoea or respiratory signs) were nevertheless communicated to the farmers. Ventilation audits were performed in four veal farms to collect practical examples including fumigation tests. The main problems on the farms were hypoventilation and draught. To stimulate correct dosing, heart girth measurements were performed on 698 veal calves (6 herds), and the association with body weight was determined by linear regression. In this way, farmers could more accurately estimate body weight by a simple heart girth measurement. Finally, to what considers individual treatments made by

the farmer, 'avoiding the use of two or more antimicrobials' was made one of the central one-liners in the communication campaign.

Conclusions: Overall the campaign was focused on a correct stable ventilation, correct dosing of a single antimicrobial with the least importance for human medicine and avoiding group treatments. The methods used and the action points identified in this project might aid other countries with similar industries to create awareness about responsible antimicrobial use.

Comments: Special acknowledgement for the important contribution of Magali Blomme to this project

Antimicrobial Resistance profiles of bacteria of Medical and Veterinary importance found in the bovine gut and the farm environment

Romy Tuin¹·Simon Gould¹·Tim Potter²·Gary Forster-Wilkins¹·James Denholm-Price¹·Mark Fielder¹

¹Kingston University, Kingston upon Thames, ²Westpoint Veterinary Group, Horsham, United Kingdom

Objectives: Antimicrobial resistance (AMR) is a threat to modern medicine. Concern has been expressed about the safe use of these drugs and their future efficacy. Although antimicrobial usage on farms was implicated as a potential driver for the selection of resistant bacteria, little is known of pathogen and AMR profiles on UK beef and dairy farms. The project will identify carriage of resistance markers in part of the national herd. The results will have implications for farming practice and public health with the potential of zoonotic spread of the organisms concerned.

Materials and Methods: Farms from South Central England were included in this study, with representative samples taken from both dairy and beef herds. At farm enrolment: history of antimicrobial use; type of farming undertaken; breed; milking and calving status were documented. Environmental samples from the farms were also collected and analysed over the period of the study. Targeted pathogens isolated were analysed to give a farm level assessment and changes were tracked.

Predominantly marker strains of *E. coli*, *Salmonella* sp. *Klebsiella* sp. and *Strep. faecalis* were targeted. The media used included MacConkey agar, Sorbitol-MacConkey agar, Modified Edwards agar, Brilliant green agar and Nutrient agar. Cultured organisms were then identified using a variety of standard biochemical tests to provide a metabolic profile and to identify the organisms present. Where appropriate, identification systems such as API systems were employed.

Once confirmed, the antibiotic efficacy profiles of the isolates were determined. The panel of antibiotics tested using EUCAST methodology were: 30µg cefquinome, 25µg amoxicillin, 10µg ampicillin, 30µg oxytetracycline, 30µg tylosin and 5µg marbofloxacin (antibiotic concentration/disc). The plates were then incubated at 37°C for 20 hours. After incubation the diameter of the zone of clearing around the disks were measured and recorded. Through analysis of the data collected during farm enrolment in combination with the bacteriology, risk factors for development of antimicrobial resistance and training needs were identified.

Results: The bacteria isolated from the initial farm were: *E. coli* (74.3%), *Pseudomonas* sp. (5.9%), *P. vulgaris* (6.7%), *Klebsiella* sp. (1.4%), *Corynebacterium* sp. (1.4%), *P. mirabilis* (1.4%) and *Streptococcus* sp.

(8.1%). Of all the isolates, 63% showed resistance to the antimicrobials in the panel according to the EUCAST guidelines.

Of the bacteria isolated, 31.5% were resistant to ampicillin (AMP), of which 14% were in the bovine gut (BG) and 18% was from environmental samples (ES). A total of 2.4% of isolates were resistant to cefquinome (CEF) (1.6% from the BG and 0.8% from the ES), 1.6% were resistant to marbofloxacin (MAR) (0.8% from both the BG and ES) and 49.2% were resistant to Amoxicillin (AML) (24.2% from the BG and 25% from the ES). Overall 35.5% of the resistance seen was in the BG and 26% was seen from ES. From the *Streptococci* isolated, 33% showed resistance to Tylosin (TY) (2.7% from the BG and 30.3% from the ES).

The *E. coli* isolated showed 22.6% resistance to AMP, 0.8% resistance to CEF and MAR and 33.1% resistance to AML. 2.4% of the *Pseudomonas* sp. were resistant to AMP and 4.8% were resistant to AML. *P. vulgaris* demonstrated resistance of 4.8% to AMP, 0.8% to CEF, 4.8% to AML. *Corynebacterium* sp. and *P. mirabilis* sp. showed resistance only to AML of 1.6%.

Of the bacteria isolated, 18.6% were resistant to both AMP and AML, of these 15.3% were from ES, and 3.3% were from the BG. One *E. coli* isolated from ES showed resistance to MAR as well as AMP and AML and a *P. vulgaris* also from ES showed resistant to CEF as well as AMP and AML.

Conclusions: Preliminary results show that a higher level of resistance was seen in the BG compared to the ES, however, multi-resistant isolates were more commonly seen in the ES. High levels of resistance were seen against AMP and AML. This is of concern, as they are used in the treatment of human infections. No clinical breakpoints were found for CEF, MAR and TY, so experimental breakpoints were used for these initial samples. The lack of clinical breakpoints for these drugs show that more research is needed to depict resistance in veterinary medicine. This information will help evaluate the level of antibiotic resistance on beef and dairy farms.

Anti-Microbial Resistance

P03-003-019

Impact of enrofloxacin dosing regimens in cattle on intestinal pharmacokinetics and the selection for resistant enteric bacteria

Derek Foster¹·Megan Jacob¹·Sophia Kathariou²·Mark Papich³

¹Population Health and Pathobiology, NC State University College of Veterinary Medicine, ²Food, Bioprocessing, and Nutrition Sciences, NC State, ³Molecular and Biomedical Sciences, NC State University College of Veterinary Medicine, Raleigh, United States

Objectives: The objective of this study was determine the impact of two FDA-approved dosing regimens of enrofloxacin on the active drug concentrations in the gastrointestinal tract, and to associate these concentrations with changes in the fecal bacteria of the steers.

Materials and Methods: Ultrafiltration probes were surgically implanted into the ileum and spiral colon of 12 6-month old Holstein steers. In a cross-over study, each steer was administered enrofloxacin either once (12.5 mg/kg subcutaneously) or once a day (5 mg/kg subcutaneously) for 3 days. After the sampling period and a 1 week washout, steers were reassigned to the other treatment group. Plasma, interstitial fluid, and intestinal fluid were collected during treatment and for 72 hours after the last dose for pharmacokinetic modeling. Fecal samples were collected

every 12 to 24 hours during treatment and for 7 days after the last dose. Fecal samples were collected twice a week from a subset of the calves for 1 month after the last treatment. Samples were cultured on selective media to quantify *E. coli* and *Campylobacter* spp. Ten isolates from each time point were further characterized by microboth dilution to determine the minimum inhibitory content (MIC) of enrofloxacin.

Results: Fecal *E. coli* concentrations decreased significantly immediately after treatment in both groups, but returned to baseline by 72 hr in the high dose group and 144 hr in the low dose group. The impact of dosing on *E. coli* MIC was dependent on treatment order. In the steers that received the high dose first, the median *E. coli* MIC did not change after the high or low dose. In the steers administered the low dose first, the median *E. coli* MIC increased significantly in the low dose group from time 0 to day 8, but returned to baseline by day 12. At that time, they received the high dose, and the MIC again increased significantly at day 7. All animals were positive for enrofloxacin-susceptible *Campylobacter jejuni* either by direct plating or by enrichment (or both). *Campylobacter* could not be recovered for the first 24-120h after treatment, but samples from 144-196h post-treatment were again *Campylobacter*-positive, suggesting that the populations of the organism were temporarily reduced below detection levels in response to treatment. Pharmacokinetic analysis is pending.

Conclusions: Administration of enrofloxacin by either FDA-approved dosing regimen appears to cause significant, but short-lived changes in the fecal bacteria of cattle. Associating these changes with the pharmacokinetic parameters may allow for better risk assessment models to predict the impact of systemic antimicrobial administration on shedding of antimicrobial resistant pathogens in cattle.

Antimicrobial Susceptibility Of Staphylococci Strain Isolated From Milk Of Goats Reception Pot With Mastitis The Municipality Of Tanhuato Michoacan

Carlos Bedolla ¹ Rodolfo Lucio ² Victor Manuel Sánchez ³ Hugo Castañeda ⁴ Valente Velázquez ⁵ Edith García ¹ José Carlos Bedolla ⁶

¹Microbiology Laboratory, ²Caprine Production, ³Ovine Production, University Michoacana of San Nicholas of Hidalgo, Morelia, Michoacán, ⁴Bovine Mastitis Laboratory, University Center for Biological and Agricultural Sciences. University of Guadalajara. , Guadalajara, Jalisco, ⁵Microbiology laboratory, University Autonomous of State of Mexico. Toluca, Mexico., Toluca, ⁶University Michoacana of San Nicholas of Hidalgo, Morelia, Michoacán, Mexico

Objectives: The aim of this study was to determine the antimicrobial susceptibility of staphylococci isolated from milk of goats receiving pot municipality Tanhuato, Michoacán.

To evaluate the antimicrobial resistance of *Staphylococcus aureus* strains isolated from milk of goats boat reception Tanhuato municipality, Michoacan.

Materials and Methods: The present study was conducted from May 25, 2014 to December 17, 2014, lasting 206 days. The study was carried out with 49 flocks of which an equal number of samples taken. Sampling of milk is performed using for this test tubes sterilized sealing plug in which the necessary identification previously stable are scored. The test tube was placed inclined to keep out dirt. The sampling was made directly from the milk storage tanks. The sample tube is filled with at

most two thirds. Finally the tubes were placed with the sample in a rack placed in a sealed cooler and then are transported to the laboratory of bacteriology of USAD (Unit Auxiliary Services for Diagnosis), Faculty of Veterinary Medicine and Animal Husbandry for cooling to 4 ° C and then for processing.

Identification of Staphylococci was conducted through its colony morphology, Catalase test, Gram staining, Coagulase test, test Mannitol, Gelatin and Hemolysis. The antimicrobial susceptibility testing was performed through the disk diffusion method on Mueller-Hinton agar. Staphylococcus were isolated in 29 herds in the town of Tanhuato, Michoacán

Results: Of which 21 correspond to *Staphylococcus aureus* (72.41%) and 8 developments (27.58%) Coagulase Negative Staphylococci to (ECN) (*Staphylococcus epidermidis*). In the case of *Staphylococcus aureus* was observed increased resistance against Penicillin, Sulfamethoxazole, Ampicillin and Erythromycin with 42.9%, 38.1%, 38.1%, 38.1% respectively, followed by 23.9% to Gentamicin, 19.1% Cefotaxime and Cefotaxime. Regarding the susceptibility observed in 90.4% to Cephalothin, Tetracycline and Cefuroxime, Pefloxacin and followed by 85.7% Doxycycline. In the case of ECN greater resistance to Trimethoprim was observed with 50%, 37.5% Doxycycline, Erythromycin, Ampicillin and Gentamicin with 25.0% each, whereas the more susceptible for ECN were Tetracycline, Penicillin and Cephalothin with 100%, and Pefloxacin, Cefotaxime, Cefuroxime, Cefotaxime with 87.5%.

Conclusions: It is concluded that the isolates of *S. aureus* and *S. epidermidis* (ECN), milk pot from reception, show different patterns of antimicrobial resistance, closely related in some cases with little chance of exposing animals in production to antimicrobial therapy, reducing bacterial selection pressure .

BVD

P03-003-022

Role of imported ruminants in the genetic heterogeneity of pestivirus strains in Northern Ireland

Maria P. Guelbenzu-Gonzalo^{1,*}Lynsey Cooper¹Ronan O'Neill²David A. Graham³

¹Veterinary Sciences Division, Agri-Food and Biosciences Institute, Belfast, United Kingdom, ²Department of Agriculture, Food and the Marine, Dublin, ³Animal Health Ireland, Carrick-on-Shannon, Ireland

Objectives: The genus pestivirus within the family Flaviviridae includes bovine viral diarrhoea virus (BVDV) types 1 and 2, border disease virus (BDV) and classical swine fever virus. The two recognised genotypes of BVDV are divided into subtypes based on phylogenetic analysis. The genetic heterogeneity of pestiviruses from clinical samples collected in Northern Ireland between 2008 and 2011 was investigated and compared to those previously described in Northern Ireland and the Republic of Ireland. In addition, the role of cattle and sheep importation in expanding the genetic diversity of these isolates was explored.

Materials and Methods: 91 BVDV positive samples from 88 herds submitted to AFBI between 2008 and 2011 were selected for further sequencing. In addition, RNA from samples from 839 bovine and 4,437 ovine animals introduced to the region during 2010 and 2011 were tested for the presence of pestiviral RNA with an reverse-transmission polymerase chain reaction (RT-PCR) assay (VetMAX Gold BVDV, Life Technologies) and the positive samples selected for sequencing. A 288 base pair portion of the 5' untranslated (UTR) region was amplified by RT-PCR and the product sequenced. The sequences were aligned and compared with the corresponding sequences of a number of reference strains and with 25 previously reported sequences.

Results: The analysis indicated that the predominant subtype circulating between 1999 and 2010 was BVDV-1a (86 samples out of 91, 94.5%). Five out of the 91 samples clustered close to reference strains in subtype BVDV-1b (5.5%). 18 out of the 839 samples from bovine animals introduced to Northern Ireland gave a positive result (2.14%, Ct<37) and 8 an inconclusive result (0.9%, Ct ≥37) comprising a total of 24 animals. A true prevalence of BVD virus positive bovine animals within those introduced was calculated as 2.9% (1.7-4%). Sequence data were obtained for eight of these samples, all of which clustered close to reference strains in subtype BVDV-1b. No positive results were obtained with the ovine samples.

Conclusions: Since only the BVDV-1a subtype was detected in samples collected between 1968 and 1999, the present study suggests that at least one new subtype (BVDV-1b) has been introduced to Northern Ireland between 1999 and 2010. BVDV-1b was also the only strain detected in imported cattle. This finding highlights the potential for the importation of cattle to introduce new strains. In contrast, the risk associated with the introduction of sheep was found to be minimal.

BVD

P03-003-023

The confirmation of the presence of Bovine Viral Diarrhea type 2 in Belgium.

Jo Maris^{1,*}

¹Animal Health, Boehringer-Ingelheim, Brussels, Belgium

Objectives: Bovine Viral Diarrhea Virus (BVDV) is often unexpectedly present in herds. Two genotypes exist: BVDV type 1 and BVDV type 2. In the USA and Canada about 45 % of the genotyped BVD strains belong to the BVDV type 2. In Europe the prevalence of type 2 is estimated at 5 %. Since the first of January 2015 an official BVD eradication program was started in Belgium. In a further evolution of BVD eradication cattle becomes more vulnerable in case of renewed virus contact. Protection on herd level by means of vaccination could prove to be a valuable tool. Therefore it is essential to know if BVDV type 2 is present.

Materials and Methods: In Belgium veterinary practitioners send in samples for diagnosis and monitoring to two official labs (DGZ - Diergezondheidszorg and ARSIA- Association regional de santé et identification d'animaux). In case of BVD analysis those labs mainly use two tests to look for BVD antigen, a BVD Ag ELISA test and a BVD Ag PCR. Analyses were carried out on different matrices. These tests however cannot make the difference between BVDV type 1 and BVDV type 2. The reference lab: CODA-Cerva, disposes of a BVD Ag PCR test which on the other hand can distinguish between BVD type 1 and BVD type 2. In order to obtain samples for further analysis two approaches were taken. First the veterinary practitioners were asked to send in samples when they had a suspicion of BVD, secondly the two official labs were asked to send all their positive BVD Ag samples to the reference lab for typing. Every matrix was analyzed except for ear notch samples. For the majority of these latter samples we don't have any information on the motives for which these samples were analyzed in the first place. This search was performed in the period between August 2014 and April 2015.

Results: Following the first approach 21 samples were sent in by veterinary practitioners. In these cases there was clearly a suspicion of BVD infection, either by clinical symptoms or by a formal positive spot test i.e. antibody search in young stock to determine virus circulation. Four of these samples were positive for BVD type 2. Two samples originated from two different animals on the same farm; in this case it concerned two confirmed PI (persistently infected) animals. The lab of DGZ in the northern part of the country has sent 113 samples to the CODA-Cerva (the reference lab). Three of those samples were positive for BVD type 2. The lab ARSIA in the southern part of the country has sent 104 samples to CODA-Cerva. Again three samples were positive for BVD type 2. In case there is already a suspicion by the vet of BVD infection up to 19 % of the samples reacted positive for BVD type 2. It concerns a limited number of samples in a limited period of time. On the other hand, samples sent by the labs DGZ and ARSIA to the lab of reference (CODA-Cerva) 2,76 % were found positive for BVD type 2. In the given period 9 samples were found positive on 8 different farms on a total of 221 samples. This results in 4 % of the samples being positive for BVD type 2. All analyzed samples originated from animals from over the country. Positive samples were traced back to different parts of the country but with a small concentration of some positive samples in the eastern part of the country.

Conclusions: The presence of BVDV type 2 is confirmed in Belgium and matches with the estimated presence of BVD type 2 in Europe. The second approach has shown that BVD type 2 is present without expecting it, since no motive was known for analyzing these samples. This unknown presence of the virus can cause hidden loss on farm level. If the vet has the suspicion of a BVD infection there is a substantial possibility BVD type 2 is present. Fourthly, when in a further evolution of an eradication program protection by vaccination is discussed one needs to be aware that it is necessary to include both types BVD in the protection.

Comments: The author was veterinary practitioner in a cattle practice for 20 years. Then he worked for three years at an Animal health service organization in Belgium. Since April 14, 2014 he joined Boehringer-Ingelheim as Field Technical Manager Cattle & Horse.

Retrospective evaluation of herd health data shows that calf mortality could be an indicator for BVDV infection.

Jeroen M. Houwing¹; Monique Driessé²¹DAP Noord - West Groningen, Winsum, ²Boehringer Ingelheim, Alkmaar, Netherlands

Objectives: Our objective was to examine whether herd health data can be used as an indicator or early warning for Bovine Virus Diarrhea virus (BVDV) circulation. Our goal is to provide the veterinary practitioner with an easy tool to be able to advise the farmer to take timely measurements on BVD.

Materials and Methods: In the Netherlands continuous animal health monitoring (CAHM) data is part of the mandatory herd held management by the vet. The vet has access to this data. Retrospective evaluation of herd CAHM data on farms with a history of BVDV circulation was performed to analyze if calf mortality could be an indicator of BVDV infection in a herd.

Three farms with a history of being BVD virus free (period 1), followed by a period of BVDV circulation in 2014 (period 2) and becoming BVDV free again (period 3) were analyzed. Retrospective data of the 3 periods per farm were evaluated and health parameters such as calf mortality were calculated. The calf mortality was also compared to the Dutch national average and the data from BVDV free farms (n=38) in the same practice. Calf mortality is defined as the number of dead calves less than one year of age divided by the total number of calves less than one year old. Data from the rendering organization and the national identification and registration system is used.

Results: During the period of Bovine Virus Diarrhea virus circulation all three farms showed an increase in calf mortality (5,75) compared to the period before (0,54) and after (2,25). Also compared to the Dutch national average calf mortality of 3,23 calves in the same year (2014), the calf mortality on farms with Bovine Virus Diarrhea virus circulation was increased.

The average calf mortality of 2,57 on the Bovine Virus Diarrhea virus free herds in the same practice was lower than the Dutch national average.

Conclusions: The results shows that calf mortality seems to be lower on BVDV free farms and higher on farms with BVDV circulation. Herd health data, such as calf mortality, can be used as indication for BVDV circulation. This data can be monitored by the vet even without being on the farm. The vet has an extra tool to advise the farmer to take timely measurements on BVD.

P03-003-025

Variability Of Bovine Viral Diarrhea Virus In Type 1A Persistently Infected Calves

Frank Van Der Meer¹; Adam Chernick¹; Karin Orsel²¹Ecosystem and Public Health, ²Production Animal Health, University of Calgary Veterinary Medicine, Calgary, Canada

Objectives: Bovine viral diarrhoea virus (BVDV), a Pestivirus in the family Flaviviridae, is an economically important pathogen of cattle worldwide. The primary propagators of the virus are immunotolerant persistently infected (PI) cattle, which shed large quantities of virus throughout life. However, up to now very little was known regarding the viral population structure in these animals. The goal of this study was to describe the extent and distribution of BVDV variability in multiple body compartments of naturally infected PI cattle derived from a Western Canadian beef herd using next generation sequencing techniques.

Materials and Methods: A cow-calf herd with a no vaccination policy experienced an introduction of BVDV in their BVDV naïve herd during, or just shortly following the 2013 breeding season. This season is 2 months during summer as is common in Alberta. Due to this short timeframe the fetuses were in approximately the same state of their development when they became infected with BVDV. In the fall of 2014 a cohort of 26 PI calves were identified, all likely infected from the same source. The calves were purchased, euthanized, and a variety of fluids and tissues including serum, mesenteric lymph nodes and obex were collected. PCR amplification of the viral genome was followed by sequencing on an Illumina MiSeq. Genomes were assembled using MIRA against a reference strain and variant profiles were constructed at the nucleotide and amino acid levels. These profiles were compared to identify putative host- and tissue-specific mutations.

Results: Parts of the genome that are known to accommodate rapid changes (E2, NS2-3) also had a large variability in the studied PIs. Surprisingly, we found a substantial variability in certain regions of NS5b, a region generally considered as very conserved. Whether this variability is a characteristic of this specific virus strain or a more general finding in PI-derived BVDV using our analysis techniques warrants further investigation. Variant analysis shows hot-spots of variability in the E2, NS3, and NS5B regions of the genome. These areas tend to differ from the group mean variant profile more often than other genomic regions. There appears to be a stretch of very variable amino acid positions at position 1710-1750 of the amino acid sequence. These mutations include a variety of frame shifts and single amino acid changes. Although not previously documented, given that these mutations are occurring in the NS3 gene it is likely that they can contribute to biotypic conversion from noncytopathic to cytopathic strains and the subsequent induction of fatal mucosal disease.

Further work to understand the phenotypic importance of these observations is needed, but it is clear that BVDV exhibits a remarkable variability within and between PI animals.

Conclusions: A major driver of evolutionary change of viruses is the immune system, however, despite the absence of an acquired immune response against BVDV in these PI cattle, there are strong indications of viral variability that is of clinical and epidemiological importance. Our results demonstrates that the virus proteins can be modified in their amino acid structure leading to new strains and changes in their pathogenic properties. Understanding the extend and nature of these genetic changes will enable us to improve our responses through optimization of future vaccine development.

Guidelines developed by the Australian Cattle Veterinarians organization for systematic management of BVDV in both beef and dairy production systems

Enoch Bergman¹; and Prof Michael Reichel, Dr Khyle Stewart, Dr Craig Wood, Dr Scott Parry, Dr Paul Cusack

¹Australian Cattle Vets, Brisbane Qld, Australia

Objectives: The objective was to develop two stand alone beef and dairy BVDV management guides as resources to Australian Cattle Vet members to assist them in controlling and managing BVDV for their clients utilizing the tools available to them within Australia. The ultimate aim was to enable veterinarians to develop cost effective programs to define, manage, and monitor BVDV on their client's farms, accounting for Australia's varied farming practices.

Materials and Methods: With assistance from the Australian Cattle Veterinarians, a special interest group of the Australian Veterinary Association, a working group comprised of six veterinarians developed both a beef and dairy oriented management guide. The working group workshopped the guides over a series of face to face meetings, via teleconference, and via email. The first section of the guides related to the epidemiology and pathophysiology of the disease. The second section discussed the tools available to Australian veterinarians to manage the disease. The final section was designed to guide veterinarians by detailing testing options and control strategies. A series of flow charts were developed to accompany the advice.

Results: A complete beef and a complete dairy set of guidelines were each developed. The guides provide veterinarians tools to structure their advice to assist their client to understand the mechanisms by which BVDV is both transmitted and maintained on properties. The guide provided veterinarians a synopsis of the outcomes associated with exposure to the virus at varying stages of gestation, attempting to simplify their ability to relate the topic to their clients. The guide outlined the tools available to measure BVDV antibody levels, to identify PI animals, and to provide immunity via vaccination. Lastly, the guidelines provide step by step decision trees to assist veterinarians to cost effectively manage BVDV, creating a value proposition by utilizing immune status to discern the need to either vaccinate or screen groups for PI's.

Conclusions: The guides were produced by the Australian Cattle Veterinarians, a branch of the Australian Veterinary Association, as a tool for veterinarians working with cattle in Australia. The tools provided allow for cost effective management of BVDV relying on either vaccination or PI hunting dictated by serology. The strategies outlined allow for systematic herd level eradication and monitoring utilizing a value proposition rather than blanket approaches, making it far more palatable for Australian producers.

Evaluation of 6 commercial ELISA kits for the detection of BVDV-specific antibodies in serum and milk using a large collection of field samples

Miet De Baere ¹, Jean-Baptiste Hanon ^{1,2}, Camille De la Ferté ¹, Sophie Roelandt ², Yves Van der Stede ², Brigitte Cay ¹

¹Unit enzootic and (re)emerging viral diseases, ²Unit coordination of veterinary diagnosis, epidemiology and risk assessment, Veterinary and Agrochemical Research Centre (CODA-CERVA), Brussels, Belgium

Objectives: Serological surveillance using antibody ELISAs is a commonly used tool to ascertain freedom of disease. Based on a previous study, 6 ELISA kits were selected for evaluation on a large number of serum and milk samples obtained in the field. The study goal was to evaluate performance characteristics of these kits and to verify

the observed lack of sensitivity of blocking ELISAs in serum and of milk testing, to evaluate whether pools of sera/individual milk samples can be used, and to assess whether it is possible to certify/monitor "BVD free herds" by means of serology on serum and/or (bulk) milk samples in the Belgian BVDV control programme.

Materials and Methods: 51 herds representative for the Belgian cattle sector (location, herd type, herd size, BVD status and vaccination status) were visited once. Serum samples were taken from all young stock (6-18 months) and from 20 randomly selected cows (mixed herds: 20 dairy and 20 beef cows). In dairy herds, one bulk milk sample and individual milk samples from the same cows which had been sampled for serum were taken. During the visit a questionnaire was filled out with the farmer to collect epidemiological information regarding BVD in their herd and vaccination, to be able to assign a BVD status to each herd: BVD free; BVD eradicated; BVD controlled; BVD infected less than 1 year; and BVD infected.

6 ELISAs were selected: 2/1 blocking and 2/1 indirect ELISA for serum/milk. Depending on the outcome of all ELISAs and using the virus neutralisation test (VNT) as a gold standard for serum, each serum and milk sample was assigned a positive, negative or discordant serological status. Next, all sera from unvaccinated herds were tested in VNT and VNT results were used as a reference for both serum and individual milk samples from the same animal. Using 2 by 2 tables we calculated true and false positive/negative results for each ELISA. These results were imported in STATA to calculate sensitivity (Se), specificity (Sp), Youden index, positive and negative predictive values, Kappa of Cohen and area under ROC curve.

Finally, weak/strong positive sera and individual milk samples were diluted in negative serum/milk to mimic pooled sera or bulk milk. Diluted samples were tested and analyzed.

Results: 3159 sera, 557 individual and 28 bulk milk samples were tested using 6 BVDV ELISAs and were assigned a positive, negative or discordant status. For serum samples, the percentage of positive samples was slightly higher for the indirect ELISAs than for the blocking ELISAs. For milk, the blocking ELISA performed better, though not significant, than the indirect ELISA, since the percentage of positively identified samples (73,2%) was similar to the percentage of the corresponding sera (75,9%), whereas the indirect ELISA seemed to be less sensitive (64,6%).

To assess the performance of each ELISA, only field samples (1308 sera and 293 individual milk samples) from unvaccinating herds (19) were used to exclude interference of vaccination. 3 out of 4 evaluated ELISAs on serum scored well for all parameters, whereas the anti-E0 blocking ELISA showed a lack of Se (93%), compensated by an increased Sp (99,1%). For milk, the blocking ELISA gain performed slightly better than the indirect ELISA both in terms of Se and Sp.

Pooling of serum and milk samples was investigated in each of the selected ELISAs since pooling of sera could reduce the costs of testing and to mimic bulk milk samples which are convenient and cheap samples to obtain. Our study showed that pooling should not be performed, since weak positive sera and individual milk samples were missed by all evaluated kits at small pool sizes. We also found that at this moment, a bulk milk sample does not reflect the BVDV status of a herd, since even in free or cleared herds a large proportion of cows are seropositive.

Conclusions: All kits performed well on individual serum samples, observing no difference between blocking or indirect ELISAs for samples from non-vaccinating herds. This led to the decision that both types of kits may be used for serological monitoring of BVDV free herds using individual serum samples in the Belgian BVDV eradication programme in the future. The decreased Se of the ELISAs using individual and pooled milk samples as a matrix and the finding that a bulk tank milk sample does not reflect the BVD status of a herd at the moment, indicates that it may be impossible to guarantee a "BVDV free" status of a herd based only on bulk milk testing.

BVD

P03-003-028

Nanowire-based electrochemical detection of anti-Bovine Viral Diarrhoea (BVD) antibodies in bovine serum

Niamh Creedon^{1*} Armelle Montrose¹ Riona Sayers² Alan O' Riordan¹¹Nanotechnology, Tyndall National Institute, Cork, ²Animal & Biosciences, Teagasc, Moorepark, Fermoy, Co. Cork, Ireland

Objectives: Rapid identification of BVD seroconverting individuals is essential in preventing costly outbreaks in naive herds. This is especially true in countries where BVD eradication is underway or complete. There is an unfulfilled need for new diagnostic techniques, suitable for on-farm analysis, that deliver early identification of virally exposed individuals, and yield the opportunity for immediate centralised data collection through remote devices. In this work we present an electrochemical on-chip fully integrated nanowire based immunosensor device for detection of BVD antibodies (Ab) in both buffer and serum in 20 minutes.

Materials and Methods: Gold nanowires electrodes, on-chip gold counter and platinum pseudo reference electrodes were fabricated on wafer-scale silicon substrates using hybrid e-beam/optical lithography, metal deposition and lift-off techniques. The on-chip nanowire electrodes were first modified with an electrodeposited polymer, using cyclic voltammetry. The carboxylic terminated polymer was activated using a mixture of EDC/NHS which allows for covalent immobilisation of the BVD capture molecules, i.e. BVD virus. The chip was then immersed in ethanolamine for 30 minutes to block the un-reacted active sites on the nanowire. Finally, the modified electrodes were exposed to known concentrations of Ab solution in phosphate buffered saline (PBS) for 20 minutes to confirm the suitability of the nanowires for label-free immunoassay applications. Each step of the assay was characterized electrochemically, illustrating a layer-by-layer build-up on the nanowire surface. The assay was repeated using serum samples again incubated for 20 min at room temperature. BVD virus and BVD monoclonal Abs specific to the envelop glycoprotein (Erns) of the virus were sourced commercially (APHA Scientific, UK).

Each step of the modifying process was electrochemically characterised using cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS). These experiments were performed in a 10 mM PBS solution containing 1 mM ferrocene monocarboxylic acid (FcCOOH) as a redox probe.

Results: The layer build-up from the functionalisation process, limits electron transfer of FcCOOH to the electrode. i.e. CV intensity decreased while the nyquist semicircles increased. Following immobilisation of BVD virus, the CV and nyquist spectra remained very similar to the ethanolamine deposition. This showed that the virus immobilised onto the majority of the nanowire surface. On exposure to the BVD Ab solution (PBS), Ab-Ag binding exhibited a strong decrease in the CV and a corresponding increase in the measured impedance. After successful demonstration of BVD antibodies detection in buffer, the BVD virus modified immunosensor was applied to detection of BVD antibody in bovine serum of known status (positive or negative). The same successful results were achieved after the modified wire was exposed to 1% positive serum incubated for 20 minutes. To confirm the bio-functionality and efficacy of the virus capture probe and to demonstrate the specificity of the sensor against BVD antibodies the sensor was exposed to BVD negative serum. We did not see any change in the electrochemical response, indicating that the sensor has the ability to discriminate between BVD seropositive and seronegative bovine samples. These sensors can be applied to the detection of the BVD virus using the same procedure, whereby the BVD antibody is immobilised onto the nanowire and the corresponding virus is detected.

Conclusions: This is the first electrochemical-based on-chip nanowire immunosensor device, using an electrodeposited polymer, to covalently immobilize BVD biomolecules. The nanowire-based BVD virus immunosensor allows specific detection of BVD antibodies in serum in 20 minutes. The ultimate aim is to reduce assay times thereby improve the on-farm applicability of this device.

BVD

P03-003-029

Monitoring of BVDV by testing antibodies to NS3 protein in calves vaccinated with an inactivated BVDV vaccine

H. Kuijk^{1*} G. Nijhoving¹ Linda van Duijn² M. Mars² W. Theuvs³ H. Swam¹ B. Makoschey¹¹MSD Animal Health, Boxmeer, ²GD Animal Health, Deventer, ³DAC De Peelhorst, Uden, Netherlands

Objectives: On many BVDV free certified farms in the Netherlands, cattle are vaccinated with the inactivated vaccine Bovilis BVD (MSD Animal Health) to reduce the risk that new PIs are born. The BVDV free status of a farm can be monitored by 6-monthly spot blood testing of 5 calves in the age of 8 to 12 months for the presence of NS3-antibodies. Sometimes calves have been vaccinated before they have been tested. The aim of this study was to determine whether vaccination with Bovilis BVD might interfere with this monitoring system in calves.

Materials and Methods: In 8 BVDV free certified herds, 5 calves in the age group 8-12 months were vaccinated with Bovilis BVD according to manufactures instructions and 5 sentinel calves were left unvaccinated. Blood samples were taken from all calves on day 1 (first vaccination), day 28 (second vaccination), day 56, day 112 and day 168 and tested for NS3 antibodies in the Prionics BVDV ELISA. Blood samples taken on day 56, day 112 and day 168 were also tested for Virusneutralising antibodies (VNT). In one herd, blood samples from all calves between 1 and 16 months of age were tested for BVD virus.

Results: All vaccinated calves showed high VNTiters on days 56, 112 and 168. In 5 herds (A,B,C,D,E) neither vaccinated nor unvaccinated calves developed ns3 specific antibodies as measured by ELISA. In the herds F, G, H, all unvaccinated calves tested negative for antibodies as measured by ELISA. In 1 herd (F) 1 vaccinated calf showed a low titer in ELISA on day 56, but was tested negative at day 112. In 1 herd (G) 2 vaccinated calves showed low titers in ELISA on day 56, these titers were undetectable on day 112. In 1 herd (H) all 5 vaccinated calves showed moderate titers on day 56, these titers declined to very low titers on days 112 and 168. Because of the moderate titers on day 56, in this herd, blood samples from all calves between 1 and 16 months of age were tested for BVD virus. No PI animal was found.

In 6 out of the 8 herds included in this study vaccination of the calves did not at all interfere with the young stock monitoring using NS3- ELISA. In 1 herd, it was required to test an additional 5 calves by antibody ELISA to confirm the BVDV-free status. It remains unclear whether the relative high titers in the 8th herd were caused by i) the vaccination, ii) by transient BVDV infection, or iii) by infection from a PI that was already removed from the herd at the time of testing.

Conclusions: Young stock monitoring can be applied in herds vaccinated with the inactivated BVDV vaccine used in this study. All vaccinated calves developed high neutralizing antibody titers. Only a small proportion of vaccinated animals developed low, short lasting titers

of BVDV-NS3 specific antibodies as measured by NS3-ELISA, potentially hampering young stock monitoring. It is therefore recommended to either take blood samples before vaccinating or to monitor on vaccinating farms by antigen detection methods.

BVD

P03-003-030

Application Of An Indirect Elisa For The Discrimination Of Bvdv 1, 2 And 3 (Hobi-Like) Infection, Based On Anti-E2 Antibodies In Bulk Milk

Chiara Nogarol¹ Nicola Decaro² Luigi Bertolotti¹ Margherita Profitti¹ Barbara Colitti¹ Maria Stella Lucente² Gabriella Elia² Canio Buonavoglia² Sergio Rosati¹

¹Dipartimento di Scienze Veterinarie - Università di Torino, Grugliasco, TO, ²Dipartimento di Medicina Veterinaria, Università degli Studi di Bari, Bari, Italy

Objectives: BVDV is a member of genus Pestivirus in the family of Flaviviridae. In addition to the recognized species, 4 additional Pestivirus species have been proposed but remain officially unrecognized. One of these new putative species is BVDV type 3 (Hobi-like). BVDV structural protein E2 is the major target for neutralizing antibodies and represents the only target antigen for discrimination between different BVDV species based on cross-neutralization assay. In this study the E2 proteins of BVDV1, 2 and 3 were produced as secreted recombinant and employed for the development of a triple diagnostic ELISA on bulk milk samples.

Materials and Methods: To isolate the full-length BVDV1, 2 and 3 E2 genes, RNA was extracted from Madin-Darby bovine kidney (MDBK) cell cultures infected with the three field strains of BVDV using a EZ1@ Virus Mini kit V2.0 (Qiagen, Hilden, Germany) and the BioRobot EZ1 extractor. It was selected a variable region of the three sequences, in order to differentiate the three circulating virus types. Gene fragments ligated with pSecTag2/Hygro plasmid (Invitrogen, USA) allowing an efficient intracellular sorting and secretion in the medium of transiently transfected mammalian cells. Sub-confluent human embryonic kidney (HEK293T) cells were transfected according to standard protocol. Sheep were immunized with inactivated native virus preparations of BVDV 1, 2 and 3 and serum titers were normalized according to homologous neutralization assay. Checkboard titration of the recombinant antigens was carried out using normalized control sera for maximum discrimination. In ELISA protocol, milk samples were used undiluted and incubated for 120' while control serum samples were diluted 1/20 in PBS 1.25% casein. Milk samples were collected from 286 dairy farms located in the territory of Piedmont Province of Cuneo. Bulk milk of each farm was collected in pool including not more than 40 lactating animals, for a total of 393 milk pool samples. During sampling, BVDV status and vaccination program was unknown for all the dairy farms.

Results: Sequence analysis of each construct showed the correct in frame cloning of the three sequences. E2 protein expression resulted different between three types: E2 of BVDV1 resulted two logs more expressed than BVDV3. Antigen production was confirmed using sera from sheep immunized against the three viral species, diluted and used as positive controls according to neutralization test. Preliminary data underline, as expected, the presence of BVDV1 in majority of dairy herds, confirming the wide use of monospecific vaccination and BVDV1 circulation. However, in few occasions, reactivity against BVDV2 and BVDV3 was detected. Interestingly, in the latter herds, pools from the same herd reacted in a similar manner, supporting the specificity of the

ELISA signal. Further investigation in one BVDV2 positive herd allowed identification of several PI animals infected with BVDV-2a, as detected by sequencing of RT-PCR amplified UTR region and representing the first report of BVDV2 circulation identified in North West Italy. The low antibody titre against BVDV3 recorded in lactating animals older than 3 years in a second farm suggested a viral extinction as no PI animals were detected.

Conclusions: The results of the present study confirm that BVDV1 seroprevalence is high in Piedmont as it is along Italian territory, confirming both monospecific vaccination and BVDV1 circulation. However, for the first time, the circulation of unusual BVDV strains have been predicted using serological test, as in the case of an active outbreak of BVDV2 which have been recognised in Italy a couple of times. This new assay therefore represents an useful tool for large scale monitoring of unusual and atypical pestivirus, leading to assess herd immune status or active circulation versus three BVDV species.

BVD

P03-003-031

Risk of pestivirus contamination of bioproducts used for immunoprophylaxis and diagnostic purposes

Aleksandra Antos¹ Julia Kęsiek-Maliszewska¹ Magdalena Larska¹

¹Department of Virology, National Veterinary Research Institute, Pulawy, Poland

Objectives: The contamination of fetal bovine serum (FBS) with pestivirus, especially Bovine Viral Diarrhea Virus (BVDV) is a common problem of concern for the safety of vaccine, plasma-derived bio-products, which may also influence the results of cell culture-based diagnostic testing. In the recent years, the new pestivirus species including BVDV-2 and Hobi-like virus emerged in Polish herds. The main objective of the study was the assessment of the risk of pestiviral transmission by defining the levels of contamination of vaccines with pestiviruses which are used in cattle management and immunoprophylaxis, as well as FBS for diagnostic use.

Materials and Methods: A total of 179 vaccines against both viral and bacterial disease for use in various animal species (68 were live attenuated or marker vaccines) and 22 commercial sera originating mostly from South America and Australia including fetal bovine serum, fetal equine serum, horse serum, newborn bovine serum and newborns calf serum and were tested for the presence of BVDV and related pestiviruses. Viral RNA was extracted using QIAamp Viral RNA Mini Kit (QIAGEN, Hilden, Germany). All samples were tested for the presence of BVDV viral genome by RT-PCR and real-time RT-PCR. Pan-pestivirus primers flanking 5'UTR region of viral genome were used for standard RT-PCR, whereas in real-time RT-PCR, primers and probes specific for BVDV-1, BVDV-2 and atypical bovine pestivirus (HoBi-like) which allow species differentiation were applied. The presence of BVDV antigen was tested with commercial E^{ms} BVDV Ag/Serum Plus ELISA kit (IDEXX, Liebefeld-Bern, Switzerland). Additionally the serum samples were tested for the presence of BVDV specific antibodies using a commercial BVDV Total Ab ELISA kit (IDEXX).

Results: Contamination of pestivirus was detected in 6 (3.3%) of tested vaccines. Four vaccines were positive in standard RT-PCR and additionally BVDV antigen was detected in another two vaccines by ELISA. Only one vaccine was positive in BVDV-1-specific real-time RT-PCR while BVDV-2 and HoBi-like pestiviruses were not identified as contaminants of the vaccines. In the case of vaccines against pestivirus (BVDV, CSFV) infections, 20 out of 21 of such vaccines gave positive

result in antigen ELISA. The only antigen ELISA negative vaccine gave positive result only in real-time RT-PCR. Additionally, 7 of pestivirus vaccines were confirmed in RT-PCR and 13 in real-time RT-PCR.

Seventeen batches (31.8%) of commercial sera were found to contain at least one species of bovine pestivirus, but only twelve of those were positive in standard RT-PCR. In real-time RT-PCR, 11 batches were found positive for BVDV-1, 3 batches positive for BVDV-2, and 9 batches positive for the HoBi-like pestivirus. BVDV antigen was found only in three samples from two suppliers using antigen ELISA. None of the foetal equine serum and horse serum was antibody positive or contained viral genetic material. Specific pestivirus antibodies were detected in 4 (18.2%) commercial sera.

Conclusions: The contamination with BVDV-1, BVDV-2 or HoBi-like pestiviruses of bioproducts especially commercial FBS available at the local market and used in immunoprophylaxis and diagnostics in Poland, remains a threat for pestivirus transmission as well as may falsify the results of diagnostic test based on FBS usage. While, the risk of pestivirus infection through a vaccine seems low, the use of the vaccines contaminated with BVDV antigen may provoke seroconversion which may result in failure of BVDV eradication program.

BVD

P03-003-032

Genetic Diversity of Bovine Viral Diarrhea Virus and Frequency of Genotypes and Subtypes in Galicia (NW Spain)

Fco. Javier Diéguez¹, Eduardo. Yus², Carmen Eiras³, María Luisa Sanjuán², Manuel Cerviño⁴, Ignacio Arnaiz⁵

¹Anatomy and Animal Production Department, Veterinary Faculty of Lugo, Santiago de Compostela University, Campus Universitario, 27002 Lugo, Spain ²Institute of Food Analysis and Research (Animal Health and Epidemiology Unit), Veterinary Faculty of Lugo, Santiago de Compostela University, Campus Universitario, 27002 Lugo, Spain ³Animal Health and Production Laboratory of Galicia, Av. Madrid 77, 27002 Lugo, Spain ⁴Boehringer Ingelheim España, S.A., Prat de la Riba 50, 08174 Sant Cugat del Vallès, Barcelona ⁵Center of Agrarian Research, Carretera de Betanzos a Mesón do Vento Km. 7,5, 15318 Abegondo (Mabegondo), A Coruña

Objectives - to investigate the frequency and diversity of BVDV circulating in the Galicia region (NW Spain), during the period 2013-2016, in order to support the design of optimized control programs.

Materials and methods - 147 BVDV strains were typed from 145 cattle and 2 sheep. For analysis RNA was isolated from samples using the QIAamp Viral RNA Mini Kit (Qiagen, Manchester, UK). cDNA was synthesized from template RNA using the AffinityScript Multiple Temperature cDNA Synthesis kit (Agilent Technologies, CA, US) according to the manufacturer's instructions. Then a 288-bp DNA product from the 5'UTR region was PCR-amplified using primers 324 and 326 as previously described. Amplified DNA fragments were purified by ExoSAP-IT treatment (USB Corporation, OH, USA) and sequenced at the Sequencing and Fragment Analysis Unit of Santiago de Compostela Sequences were converted to FASTA format using Chromas Lite 2.1.1 and imported into MEGA 6. Phylogenetic trees were constructed using the neighbor-joining method and validated using bootstrap analysis with 1000 replicates. Evolutionary distances were estimated using the Kimura two-parameter method.

Results- 147 BVDV strains were typed, of which 144 (97.9%) belonged to species BVDV-1 and 3 (2.1%) to BVDV-2. Of the 147 strains, 125 (85%) were typed as BVDV-1b based on 5'UTR analysis and comparison with reference strains. The virus in other 3 samples was identified as BVDV-1e, while the viruses in 9 other isolates were most closely related to BVDV-1d and in 3 to 1p. One isolate each was assigned to groups 1a, 1h, 1k and 1l. One of the BVDV-2 isolates was classified as 2a; it came from a PI cow that was 31 months old when diagnosed and that had already calved once. Analysis of the calf (male) was impossible because he was slaughtered soon after birth. Thrombocytopenia, hemorrhage or other clinical signs attributed to highly virulent strains of BVDV-2 were not observed. The other two BVDV-2 isolates came from a sheep farm in which reproductive problems (mainly abortions) were observed. In this farm, after negative result to the Border disease virus test, BVDV was isolated, which was classified as 2d.

Conclusion - This report, the first study of BVDV genetic diversity in Galicia, indicates that BVDV-1b is the predominant group, as in other European countries. This report also identifies several BVDV types not yet described anywhere in Spain, and it shows for the first time that BVDV-2 is present in Galicia. To our knowledge, this is the largest BVDV typing study ever reported for Spain. Our results identified ten different BVDV subgroups in Galicia.

Noncytopathic bovine viral diarrhea virus 2 inhibits the expression of major histocompatibility complex II molecule DQ, not DR

Kyoung-Seong Choi^{1*}, Joon-Seok Chae², Do-Hyeon Yu³, Hyeon-Cheol Kim⁴, Jinho Park⁵, Bae-Keun Park⁶, Young-Hun Jung⁷

¹College of Environmental Science, Kyungpook National University, Sangju 37224, ²Laboratory of Veterinary Internal Medicine, BK21 Plus program for Creative for Veterinary Science Research, Research Institute of Veterinary Science and College of Veterinary Medicine, Seoul National University, Seoul 08826, ³College of Veterinary Medicine, Chonnam National University, Gwangju 61186, ⁴College of Veterinary Medicine, Gangwon National University, Chuncheon 24341, ⁵College of Veterinary Medicine, Chonbuk National University, Iksan 54596, ⁶College of Veterinary Medicine, Chungnam National University, Daejeon 34134, ⁷National Institute of Animal Science, Jeonju 55365, Korea, Republic Of

Objectives: Bovine viral diarrhea virus (BVDV) is an economically important viral pathogen that can affect on the productivity of cattle and lead to substantial economic loss on the livestock industry worldwide. BVDV infection is associated with both acute and persistent infections depending on epidemiological circumstances. BVDV exists in two biotypes, cytopathic (cp) and noncytopathic (ncp) based on their effect on cultured cells.

Materials and Methods: Blood samples were collected, bovine PBMC were isolated using Histopaque gradients, and resuspended in RPMI 1640 medium. To separate monocytes, non-adherent cells were removed, and adherent cells were washed with sterile PBS, detached from the plates, and pelleted by centrifugation at 650 g for 10 min. For virus infection, 5 × 10⁶ monocytes were added to a 6 well plate and infected with cp and ncp BVDV biotypes at the same MOI of 0.002 for 48 h. After 48 h, ncp BVDV1, ncp BVDV2, and mock-infected cells were harvested. The expression of major histocompatibility complex class

(MHC) II molecules DR and DQ in each BVDV-infected monocytes was measured by western blot, flow cytometry and real-time RT-PCR.

Results: The results showed that ncp BVDV1-infected monocytes displayed the expression of total MHC class II on their surface by flow cytometry, which showed a similar expression of mock-infected cells. In contrast, there was significant down-regulation in ncp BVDV2-infected cells. However, the expression of DR in ncp BVDV2-infected cells was unchanged compared with DQ expression. The expression of DQ by real-time RT-PCR was markedly reduced in ncp BVDV2-infected cells. A significant reduction in the levels of DQ protein was observed in ncp BVDV2-infected monocytes compared with ncp BVDV1-infected cells. Taken together, these results indicate that the down-regulation of MHC class II in ncp BVDV2-infected monocytes is due only to the reduction of DQ, but not DR.

Conclusions: Our results suggest that ncp BVDV2 inhibits antigen presentation to immunocompetent T cells compared to ncp BVDV1 infection. The present results suggest that ncp BVDV2 fails in performing viral control and clearance as well as has detrimental effects in the animals, which results in defective antigen presentation, enhanced virus dissemination, and severe immunosuppression. Our results thus provide insight to better comprehend the pathogenesis of ncp BVDV2 infection.

P03-003-034

BVD testing strategies in neonatal calves: serial application of ELISA and real time RTPCR and evaluation of the potential "diagnostic gap"

Ronan O'Neill¹·Clare Gallagher¹David Graham²

¹Virology, Central Veterinary Research Laboratory, Dublin, ²Animal Health Ireland, Carrick on Shannon, Ireland

Objectives: All Irish calves are tested for BVDV as part of a national eradication programme. After an initial positive or inconclusive result, a confirmatory test on a blood sample may be used to distinguish persistent from transient infections. This testing must take into account the potential for false negative results due to maternally derived antibodies (diagnostic gap) when using ELISAs. However, individual rRTPCR testing is costly. Therefore samples are screened by ELISA, with negative samples further tested by rRTPCR. The objective of this study was to investigate the performance of both tests with particular emphasis on the diagnostic gap.

Materials and Methods: The national eradication programme permits animals with a positive or inconclusive result on an initial tissue tag test to be subjected to a confirmatory test to determine if it is persistently or transiently infected with BVDV. A commercial BVD antigen capture (Ag) ELISA (IDEXX) was performed according to the manufacturer's instructions on 6,497 serum samples submitted for this purpose to the Central Veterinary Research Laboratory in 2013. RNA was also extracted from these samples using an automated extraction robot and tested for BVDV by real time RTPCR. Samples with cycle threshold (Ct) values below a pre-set cut-off limit were considered positive. A BVD Virus Neutralisation Test (VNT) in a microtitre format was performed in serial twofold dilutions up to 1/4096 on a subset of heat-inactivated serum samples.

Results: Of the 6,947 calf samples tested, 1,921 (28%) were found to be negative on Ag ELISA and were retested using BVD rt-PCR. 285[DG1] of these proved ELISA negative/PCR positive (ENPP) (indicating a

diagnostic gap in 4% of samples). Both the age at blood sampling and the interval between initial ear notch and confirmatory blood sampling were significantly lower in this ENPP group at 46.1 and 35.7 days respectively, compared calves whose confirmatory blood samples tested positive by ELISA (62.0 and 49.1 days respectively). The rtPCR results for this ENPP group showed a range of CT values, with 17% having Ct>34 and 4% having Ct<25. The serology results for this group showed a range of titres. While 44% of samples had high titres (>1/4096), 5% of samples had titres < 1/8.

Conclusions: The ELISA is a robust assay well suited to disease eradication programmes, but has a lower analytical sensitivity than rRTPCR and is susceptible to interference from BVD-specific antibodies in serum. Reliance on ELISA testing alone would result in 4% false negatives, highlighting the importance of further testing of ELISA-negative samples by rRTPCR to individual farms and control programmes alike. Based on this study, negative ELISA results on serum samples are only accepted within the Irish eradication programme when they come from calves aged over 75 days.

BVD

P03-003-035

Detection Of Infectious Bovine Rhinotracheitis, Bovine Viral Diarrhea And Bovine Respiratory Syncytial Viruses In Nasal Exudate From Calves By RT-PCR

Vincent Robles¹·Santiago Casademunt¹Pere Ordís¹

¹Hipra, Amer (Girona), Spain

Objectives: This study shows the results obtained from 5 years samplings with a diagnostic tool (BOVIRESP®) based on Real Time (RT-PCR) analysis to determine the presence or absence of Infectious Bovine Rhinotracheitis virus (IBRV), Bovine Viral Diarrhea virus (BVDV) and Bovine Respiratory Syncytial Virus (BRSV) in nasal swabs from calves suffering acute outbreaks of respiratory disease in Spanish feedlots.

Materials and Methods: A total of 1.614 nasal swabs have been analyzed from pneumonic calves from 2009 to 2013. Nasal exudate from 6 different calves from one feedlot with suspicion of virus shedding were collected using the diagnostic kit. Refrigerated samples were sent to DIAGNOS (HIPRA, Spain). Once in the laboratory, automated extraction of viral DNA and RNA (QIAmp DNA and RNeasy minikit, Qiagen) was realized (QIAcube, Qiagen), then specific amplification of IBRV, BRSV and BVDV genetic material was realized through three different RT-PCRs adapted from previously described protocols. A final report with RT-PCR results was generated for each specific farm. Data generated in reports from 2009 to 2013 was analyzed.

Results: A total of 269 reports were delivered. One hundred and five of these reports (39%) were positive to at least one of the analyzed pathogens. Fifty-four (51.4%) of these reports were RT-PCR positive to BVDV, 50 (47%) were positive to BRSV and 14 (13%) were positive to IBRV. Thirty reports (12.3%) were positive to more than one analyzed virus. In 48% of BRSV-positive reports, samples had been collected between September and December (autumn in Europe). Samples from IBRV and BVDV positive reports had been collected along the year without observable differences. In contrast with the clinical perception of many veterinarians, it is noteworthy that the most common isolated pathogen is BVDV. This fact suggests a potential major participation of this virus in the Bovine Respiratory Disease (BRD) etiology, probably as an immunosuppressor. The seasonality of the detection of positive animals to BRSV is remarkable, being greater in autumn.

Conclusions: This diagnostic kit (BOVIRESP®) based on RT-PCR is currently well established as an important tool of diagnostic support for the veterinary practitioner. The results obtained suggest the necessity of studying more deeply the pathogenic role of BVDV in BRD, as well as considering BRV as a frequent viral pathogen in BRD.

P03-003-036

Evaluation of the presence of antibodies to BVDV I and II in cattle on a farm with rigorous control on the transit of animals

Claudia Ribeiro¹; Rui Machado²; Ricardo S. Jordão³; Eliana D. Stefano¹; Liria H. Okuda¹; Adriana H. D. C. N. Romaldini¹; Edviges M. Pituco¹

¹Research and Development Centre for Animal Health, Instituto Biológico, São Paulo, ²Embrapa Southeast Livestock, São Carlos, ³Laboratory Immunobiological Production and Supplies of the Instituto Biológico, Instituto Biológico, São Paulo, Brazil

Objectives: BVDV is a worldwide spread disease in most countries there is a high rate of seropositive animals above the age of three years, ranging between 60 and 90%. The great antigenic diversity observed among isolated strains of BVDV has special meaning for epidemiology, diagnosis, immunization strategies and control of the disease. The objective was to verify the presence of antibodies and cross-neutralization against BVDV - I and BVDV - II. Also assess whether the fact of not having traffic farm animals helps control BVD.

Materials and Methods: This study used 114 female cattle, aged 02-84 months herd for milk and unvaccinated for BVDV, coming from herds located in the city of São Carlos, São Paulo, Brazil. It is a closed herd, meaning there is not transit animals. Two harvests were performed, the first Jan / 2015 and the second Feb / 2015, ie, one month apart. The serodiagnostic was conducted by the VN method, as described by OIE, using the BVDV-I NADL and BVDV-II strains VS253. The test cutoff point was 10. The samples were serially diluted in log base 2, from the 1:10 dilution to 1: 5120. The property has a history of abortion, of the 114 evaluated animals, 14 animals showed abortion along its life.

Results: The animals studied only 7% (8/114) were positive for BVDV -I, these five were reactive to both the strains used. The analysis with BVDV -II revealed that 5% (6/114) animals had antibodies against this strain . The antibody titers ranged from 10 to 320 for BVDV -I, the titers were lower when compared to BVDV -II, the highest titer BVDV-I was 80 and higher for BVDV-II was 320. Surprisingly the amount of positive animals is much lower than expected. None of the 14 animals that have aborted any time during their life presented titer of antibodies against BVDV-I and BVDV-II. Surprisingly the amount of positive animals is much lower than expected. None of the 14 animals that have aborted any time during their life presented titer of antibodies against BVDV-I and BVDV-II.

Conclusions: It is concluded that there was a low frequency of occurrence of bovine reagents to BVDV. It was demonstrated that to use of more than one viral strain, increased the sensitivity of detection of seropositive animals in the VN. The farm maintains rigid control of the animals, and the low percentage of positive animals shows that the handling and care of infectious diseases are valuable tools now to maintain low levels of BVD. Abortions property can not be linked infectious causes, since none of the animals with a history of abortions had title virus detection.

BVD

P03-003-037

Quantifying The Risk Of Spread Of Bovine Viral Diarrhoea Virus (Bvdv) Between Contiguous Herds In Ireland

Tracy Clegg¹; David Graham²; Hans-Hermann Thulke³; Pdraig O'Sullivan⁴; Guy McGrath¹; Simon More¹

¹Veterinary Sciences, University College Dublin, Dublin, ²Animal Health Ireland, Carrick-on-Shannon, Ireland, ³Ecological modelling, Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany, ⁴Irish Cattle Breeders Federation, Bandon, Ireland

Objectives: The control of bovine viral diarrhoea virus (BVDV) mainly focuses on the identification and restriction of persistently infected (PI) animals. However, other transmission pathways can also result in new breakdowns, including the movement of animals pregnant with PI calves and the spread of infection between contiguous farms. Contiguous spread is likely an important problem in the BVD eradication programme in Ireland, given the spatial distribution of residual infection, and the highly fragmented nature of land holdings on many Irish farms. The objective of this study was to quantify the risk of BVD spread between contiguous herds in Ireland.

Materials and Methods: Multivariable logistic regression models were used to estimate the infection risk of a herd having BVD positive calves in January to June 2014 (the study period) when contiguous to a herd that had at least one BVD positive calf born in 2013. The models included risk factors relating to the study herd and to neighbouring herds. Separate multivariable models were built for each of four "PI-neighbour" factors relating to the presence of BVD+ animals and/or the presence of offspring of PI breeding animals.

Results: In total, 58,483 study herds were enrolled. The final model contained the province, the log of the number of calf births registered during the study period, the number of cattle purchased between January 2013 and January 2014, and with a two-way interaction between the number of animals of unknown BVD status in the study herd and the PI-neighbour risk factor. When the number of PI-neighbour herds was used as the PI-neighbour risk factor, the odds ratio (OR) associated with the number of PI-neighbour herds ranged from 1.07 to 3.02, depending on the number of unknown animals present. To further explore the risk associated with PI-neighbour factors, the models were repeated using a subset of the study herds (n = 7,440) that contained no animals of unknown status. The best fitting model including "any PI-neighbour" as the PI-neighbour factor and also contained the log of the number of calf births registered during the study period and the number of cattle purchased. The OR associated with "any PI-neighbour" was 1.92 (95% C.I. 1.37-2.70).

Conclusions: This study provides the first quantitative information on the risks posed by the presence of BVD+ animals in neighbouring herds and also highlights the importance of clarifying the BVD status of animals that have not yet been tested in the context of the Irish eradication programme.

P03-003-038

Lessons learnt from a cross-sectional field survey: how to implement serological monitoring of BVD-free herds in the Belgian BVDV eradication program?

Jean-Baptiste Hanon¹ Miet De Baere¹ Camille de La Ferté¹ Sophie Roelandt² Brigitte Cay¹ Yves Van der Stede²

¹Unit enzootic and (re)emerging viral diseases, ²Unit coordination of veterinary diagnosis, epidemiology and risk assessment, Veterinary and Agrochemical Research Centre (CODA-CERVA), Brussels, Belgium

Objectives: In order to provide recommendations regarding serological surveillance strategies to certify and/ or monitor freedom of infection in Belgian herds using BVDV-specific antibody ELISAs, 51 Belgian herds were sampled and serological results were analysed taking into consideration epidemiological parameters at the individual and herd level. The epidemiological data was collected through a questionnaire filled out in each of the visited farms the day of sampling. Factors with relation to age of sampled animals, sample matrix, type of ELISA, number of animals to sample, design prevalence and vaccination status were evaluated.

Materials and Methods: 51 herds representative for the Belgian cattle sector were visited once. Serum samples were taken from all young stock (6-18 months) and from 20 randomly selected cows (mixed herds: 20 dairy and 20 beef cows). In dairy herds, one bulk milk sample and individual milk samples from the same cows sampled for serum were taken. All samples were tested for BVDV-specific antibodies using different ELISAs and a positive, negative or discordant final serological status was assigned to each sample. An animal-level database was created in Excel® for all individual samples with other variables (ID, age, sex, herd type,...) extracted from the national livestock databank (SANITEL).

During the visit a questionnaire was filled out to characterize each herd and to collect epidemiological information regarding BVD status, control measures in place, vaccination practices, risk factors for BVD introduction, detection of PI animals in the herd,... Answers were recorded in a herd-level Access® database. Then, a BVD status was assigned to each herd: BVD free; BVD eradicated; BVD controlled; BVD infected less than 1 year; and BVD infected.

Using SAS 9.2.® software, the 2 databases were merged taking the herd ID as matching variable. Descriptive statistics were performed to identify factors that influenced the serological status of samples and herds. Subsequently these factors were included as covariates in a univariate logistic regression using the serological status of the sample as dependent (response) variable. Significant covariates were kept and put in a final multivariable logistic model.

Results: Among several explanatory variables, herd production type, participation to auctions, vaccination status against BVD, age of the animals as well as BVD status of the herd clearly influenced the obtained serological results. After considering the seroprevalence observed in function of age class, vaccination and BVD herd status, the following recommendations were given to the stakeholders with relation to serological monitoring of BVD-free herds:

- serological monitoring should preferably be performed in animals at the age of 6 up to 18 months.
- only unvaccinated animals should be sampled for serological monitoring.
- bulk milk testing cannot be used at this stage to monitor the possible exposure of the herd to BVDV infection.
- a case detection protocol is advised for annual serological monitoring

of BVD-free herds, designed to detect a minimum prevalence of 15%, with a higher seroprevalence indicating a possible recent circulation of BVDV in the herd.

- annual monitoring of BVD-free herds can be performed by testing 15 to 19 young unvaccinated animals in function of herd size. All tested animals should be seronegative.
- Alternative strategies to monitor BVD-free herds: continuous testing for BVDV of all new-born calves, annual Ag testing of all animals which have not yet been certified non-PI, serological annual testing of larger number of animals to evaluate the herd seroprevalence with an acceptable precision,... The choice of the monitoring system should be adapted to each herd and should take into account practicability and financial cost in function of the herd size.

Conclusions: This cross-sectional serological survey coupled with an epidemiological survey delivered very useful data and information to anticipate the serological monitoring of BVD-free herds in the Belgian BVDV eradication programme initiated in January 2015. It has been shown that serological monitoring can be used as a tool to maintain a BVD-free herd status provided that it is adapted to the epidemiological field situation and in particular takes into consideration age of the animals, vaccination status and herd seroprevalence observed in function of exposure to BVDV.

BVD

P03-003-039

Assessing testing of serum pools as a cost-effective method for establishing the bovine viral diarrhoea (BVD) status of a herd

Maria P. Guelbenzu-Gonzalo¹ Lynsey Cooper¹ David A. Graham²

¹Veterinary Sciences Division, Agri-Food and Biosciences Institute, Belfast, United Kingdom, ²Animal Health Ireland, Carrick-on-Shannon, Ireland

Objectives: Bovine viral diarrhoea (BVD), caused by infection with bovine viral diarrhoea virus (BVDV), is one of the most economically important endemic diseases of cattle. Within disease control programmes, serology is often used as a rapid and cost-effective intermediate step to identify herds that are likely to contain persistently infected (PI) animals before proceeding to whole herd testing. The objective of the present study was to evaluate the use of serum pools as an alternative to the testing of individual samples for the detection of antibodies to bovine viral diarrhoea virus (BVDV) using a range of enzyme-linked immunosorbent assay (ELISA).

Materials and Methods: Between 5 and 10 serum samples from young stock (12-14 months) from 300 herds participating in a BVD seroprevalence study in Northern Ireland and representing a range of 'within herd [sample] prevalence were initially tested for antibodies to BVDV using a p80 ELISA kit (LSI Vet BVD/BDV p80 blocking one step kit, Life Technologies). Of these, 135 were vaccinating the herd for BVD with an inactivated vaccine and 165 were not. Thereafter serum pools consisting of an aliquot from each individual sample tested per herd were prepared and tested with a range of p80 and whole virus antibody ELISA kits and protocols. Results obtained were compared to the proportion of seropositive animals in each pool as tested with the LSI p80 kit using the individual sample protocol. The characteristics of the tests used were evaluated using WinEpiscope 2.0 (<http://www.clive.ed.ac.uk>).

Results: When testing the whole set of herds, all kits except one of the

protocols described for the LSI kit (LSI epidemiological protocol- LSI E) obtained a relative sensitivity of pooled sera relative to individual animal results of >94% (94-99.9%). All p80 kits returned a relative specificity (Sp) >87% (87-100%). The whole virus kits had a lower specificity (between 73 and 77%). Kappa values were over 0.7 for all kits with the exception of the LSI E. Three out of the five p80 protocols received a higher kappa value (>0.8) than the whole virus kits (>0.69). The other two p80 kits obtained kappa values of 0.7 and 0.35. When only non-vaccinated herds (n=165) were included in the analysis, the specificity of all the kits achieved 100%. The sensitivities however decreased slightly (between 0.5% -2.2%). Kappa values improved for all whole virus protocols and for most of the p80 kits.

Conclusions: The present study indicates that testing of serum pools for antibodies to BVD can provide a cost effective method to assess the status of a herd. Herds vaccinating with an inactivated vaccine should be tested with p80 kits in order to minimize false positive results. In herds vaccinated with a modified live vaccine, vaccine-induced antibodies will be detectable with both kits so only unvaccinated animals should be sampled. Test performance could be improved further by optimising the cut off but it should be chosen in light of the objective of the testing and with the understanding that it will have an effect in the Se and Sp achieved.

BVD

P03-003-040

Reconstructing BVDV infection in Northern-Belgium using network analysis

Stefaan Ribbens^{1,*} Jozefien Callens¹ Willem Van Praet¹ Leen Van Schoubroeck¹

¹Animal Health Care Flanders, 9031 Drongen, Belgium

Objectives: A main influencer of the spread of BVD (Bovine Viral Diarrhoea) is the trade of persistently infected (PI)-cattle. Starting from the 1 of January 2015, Belgium takes up a national BVD-control programme though systematic detection of PI cattle and banning them from trade. This abstract reconstructs the trade of (known) detected PI-animals in the voluntary phase of BVD-control (2010-2014) in Northern-Belgium through network analysis.

Materials and Methods: For a five-year period (1 Jan 2010– 31 Dec 2014) before the national BVD-control programme, all BVD-antigen test results with complete animal ID were collected. All cattle tested positive for BVD-antigen at Animal Health Care Flanders & not (re)tested negative were assumed as PI-animals and used in this analysis. Using I&R data the life-trajectory of (known) detected PI-animals with livestock movements was reconstructed. Network analysis was performed using NodeXL© and geolocation though Gephi© & Google Earth©.

Results: A directed graph or 'BVD PI-network' of 3,052 vertices (cattle farms) and 4,011 Edges (PI-transports) was constructed. Graph accounts for (known) detected PI-movements between 3,052 cattle and veal calf herds . The actual trade of PI-animals is underestimated since Not all PI animals were detected (e.g. only approx. 10% of annual traded animals is tested at purchase). The actual dispersion of BVD is underestimated since other transmission routes are not graphed (e.g. transiently infected animals, Trojan pregnant cows, indirect transmission, etc.).

Conclusions: There was evidence of (temporarily) presence of PI-animals in 16.7% of cattle herds in Northern-Belgium. This abstracts clearly illustrates the need for a systemic control of BVD in Belgium. This

abstracts was used to help decision makers concerning the start of a national control Belgium in Belgium in 2015.

BVD

P03-003-041

Case report: Severe loss on a Belgian dairy farm presumably caused by an infection of Bovine viral diarrhea virus type 2 a

Jo Maris^{1,*}

¹Animal Health, Boehringer-Ingelheim, Brussels, Belgium

Objectives: This abstract describes a clinical case of Bovine Viral Diarrhea (BVD) on a dairy farm in the eastern part of Belgium. It all started in April 2012. After the first severe clinical symptoms the situation was monitored until BVD apparently disappeared from the farm in spring of 2015. BVDV is divided in two subtypes, BVD type 1 and BVD type 2. In the US and Canada 50 % of BVD infections are caused by BVDV type 2. In Europe this is until now approximately maximum 5 %. In this case contact with BVDV type 2 has been confirmed.

Materials and Methods: It concerns a dairy farm with approximately 179 animals present, of which 100 lactating cows. The farm is well managed and uses the zero grazing principle. April 12, 2012 the veterinarian was called in because several dairy cows became ill and an overall production drop of one third was noticed. Symptoms were high fever (>40° C), severe watery diarrhea sometimes with a hemorrhagic aspect, fast dehydration and collapse in a short period of time. Within a fortnight 17 adult cows died. Some cows in the herd developed fever but recovered. BVD was already monitored on this farm by means of a yearly spot test. I.e. Sample animals of 6 to 13 months of age for BVD antibodies to monitor virus contact. On March 29, 2012: 14 days before the massive clinical outbreak, a spot test was performed and results were completely negative. BVDV infection was suspected but could not be confirmed. Several cows were tested and tests were negative. A bulk milk test BVD Ag PCR was negative at the time of disease. Several other analyses were performed (Salmonellosis, Ehrlichiosis) but all came back negative. May 12, 2012 was the first time contact with BVDV could be confirmed, three cows were found positive for BVD antibodies. As of June 27, 2012 every newborn calf was tested by ear notch sampling with a BVD Ag ELISA test. Several calves were negative but October 4, 2012 the first positive calf (PI) was born. The moment this calf was infected fits with the period of the severe clinical outbreak. Several calves were born positive during the next years, even after taking the best possible precautions.

Results: August 27, 2014 the veterinarian was asked to examine two sick animals. These two heifers 21 months of age were found positive BVDV type 2 but both tested negative at birth by BVD Ag ELISA on an ear notch sample. One died acutely and probably suffered an acute transient infection. The other one was always a poor doer. This animal was euthanized and by examination of lymph nodes, organs and ear tissue it could be confirmed as a PI animal. Because of the level of virus (Cycle time values PCR) found in every organ and tissue. The virus was identified as BVDV type 2 a. The respective mothers of these animals tested negative but both animals showed antibodies with a more elevated level against BVDV type 2. September 30, 2014 the whole herd was sampled and tested for BVD Ag. No PI animal was identified. After that on March 6, 2015 again a PI was born and the infecting virus was identified as the same BVDV type 2 a. In January 2015 vaccination was started. Another calf, last one in row, was born positive on June

4, 2015. This calf must have been infected at a time were no other PI animal was present on the farm, because on September 30 2014 all herd was screened. The mother of this calf was bred in September the only possible time of infection to develop a PI could take place between October 2015 and January 2016. This infection had to be caused by transient infected animals on the farm.

Conclusions: The origin of the first disease outbreak in the dairy cows could not be identified. By deduction the virus BVD type 2 must have entered the farm in March 2012. The diseased heifers in august 2014 were tested negative at birth by ear notch BVD Ag ELISA. It is very likely that at least one of these test results was false negative. This case report shows that to eradicate BVD more is needed then only tracking PI's and eliminating them. Diagnostic testing is coming too late when it concerns BVD. In addition to monitoring new entrance of the BVD virus it is necessary to elevate bio security measures and to protect the animals by vaccination.

Comments: The author was veterinary practitioner in a cattle practice for 20 years. Then he worked for three years at an Animal health service organization in Belgium. Since April 14, 2014 he joined Boehringer-Ingelheim as Field Technical Manager Cattle & Horse.

BVD

P03-003-042

BVD control on dairy farms: a in clinic approach to engage farmers

Jos de Boer ¹;Siert-Jan Boersema ¹Monique Driessse ²

¹Van Stad tot Wad Dierenartsen, Loppersum, ²Boehringer Ingelheim, Alkmaar, Netherlands

Objectives: Bovine viral diarrhea (BVD) is an important disease and causes health and welfare issues and economic losses. Farmers want healthy cows and beneficial financial results without problems and they consider animal welfare a very important issue nowadays. Therefore they want no BVD on their farm.

The farmer-clients of this clinic are well aware of the effect of BVD and most farmers participate in a BVD control program. This is a case report of an in clinic approach how awareness was raised, to stimulate farmers to control BVD and to stay engaged.

Materials and Methods: The intrinsic motivation of the veterinarians is important. Our practice has SMART targets on BVD. For each vet records of the number of farms working on BVD control are present. BVD vaccination is part of our control program. Team agreements on the following were part of the strategy; speak with one voice: all vets have the same approach, up to date and adequate knowledge of BVD and control programs, use the AIDA model to convince and motivate farmers. AIDA model is a stepwise procedure:

Attention Bring BVD to the farmers attention. The method is depending on the type of farmer. Examples are written articles, lectures and study groups. The strategy is to keep the messages simple and uncomplicated; "BVD eradication and control is simple!"

Interest The next step: how to get the farmer really interested in BVD control. What are the losses caused by BVD on the farm? BVD control is financially beneficial. What does it bring the farmer? Repetition of easy messaging is key.

Desire Often stimulated by external factors, such as experiences of other farmers, a herd health plan or stimulated by the dairy industry.

The farmer is interested to learn more. A clear and easy approach will get him ready for the next step.

Action The farmer is ready to control BVD and willing to participate. In this part it is important that all vets have the same approach. Is the farmer convinced to start vaccinating?

Every vet or person has their own specialty depending on his or her character. Working in a team has an advantage because for every step in the AIDA model one can consult a more convincing vet.

Results: The number of farms participating in a BVD eradication and control program (including vaccination) increased in the last 3 years from 69% of the farms to 83% in 2015. The variation in the participation rate of farmers varies per vet from 74% to 100%; likely due to "inter-veterinarian" difference in competences and communication skills. The number of vaccinating BVDV free herds went up from 5% to 10% of total farms.

The motivation of the vets and farmers to control BVD has increased. By following the AIDA model and the approach as a team BVD control in this practice is considered successful.

Conclusions: BVD control should be in the hands of the vets because of their knowledge and expertise on the disease. Awareness within the team and a uniform approach of BVD control will stimulate and motivate veterinarians. This case description shows the success of this approach by the increased number of farms participating in a BVD control program and BVD vaccination.

First results of the bovine viral diarrhea control plan in Southern Belgium

Marie-Pierre Michiels ¹;Christian Quinet ¹Fabien Grégoire ¹Guy Czaplicki ¹Jean-Yves Houtain ¹

¹ARSIA (Regional Association for Animal Identification and Health) , Ciney, Belgium

Objectives: Since first of January 2015, a compulsory control plan against the bovine viral diarrhea virus (BVDV) is implemented in Belgium. This program, like in German and Luxembourg, is based on two cornerstones:

- (1) a systematic screening of the calves at birth, and of the dams giving a positive calf;
- (2) a marketing ban (except for slaughter) and an interdiction of pasture for the detected or suspected PI animals.

This study provides a descriptive analysis of the results obtained in Southern Belgium during the first nine months of the control plan.

Materials and Methods: Based on the informations retrieved from the national database of identification (SANITEL), the number of herds in which at least one birth occurred between 01/01/2015 and 30/09/2015 and the number of births were determined.

Information on laboratory analyzes and official individual BVD statutes were obtained from the national BVD database.

A PI animal was defined as a bovine having official status "PI" on 11/30/2015. This status is assigned when a bovine gets at least one positive result and no negative result afterwards.

The incidence of BVDV at birth was estimated by dividing the number of PI calves born during the examined period by the number of calves born and tested at birth during the same period.

The herd prevalence was obtained by dividing the number of herds where at least one PI calf was born during the examined period by the total number of herds where at least one birth was recorded in the same period.

Herd prevalence and birth incidence were estimated with 95% confidence intervals (95% CI) assuming a binomial exact distribution.

Statistical analysis of the data was performed using a chi-square test (Toma B. et al., 2001).

Results: The biggest part of the sampling at birth (99.4%) was achieved by using ear tags associated with ear biopsy Allflex ULTRA-TST.

0.56% of the samples performed in this way have failed, leading to the reception of an empty trocar in the laboratory. Same observations were made in Ireland (0.44%; D. Graham, unpublished).

0.53% (95% CI: 0.51-0.55) of the calves born during the period were detected PI.

In comparison, the proportion of PI calves detected at birth in Switzerland at the start of the eradication plan was 1.8% (Presi P. et al., 2011). The incidence of BVD at birth observed in Wallonia seems more favorable but remains comparable to those reported in Lower Saxony (Brackmann J. et al., 2014) and Ireland (Graham D., unpublished), which were respectively 0.75 % and 0.61%.

The proportion of herds faced with the birth of at least one PI calf during the period was 9.45% (95% CI: 8.84-10.06). This herd prevalence is lower than the estimates made before the plan and based on a serological approach by Sarrazin S. et al. (2013) which concluded that 44% of Belgian herds were faced with the presence of PI animals.

In infected herds, between 1 and 20 PI calves were born during the period. In 95% of cases, the number of detected PI was less than or equal to 7.

Only 7.2% of dams of PI calves tested were themselves PI.

Herd size with a number of more than 100 animals was significantly associated with risk of PI calves birth (OR = 3.13; 95% IC: 2.66-3.67; $p < 0.001$).

Conclusions: The first results of the BVDV eradication plan implemented in the southern part of Belgium are encouraging. Technically, farmers seem to really master ear notch sampling linked with primary identification tag. Moreover the proportion of born PI calves and the proportion of infected herds observed in the first nine months are lower than preliminary estimates. However, these first elements do not allow us to predict the effectiveness of the plan or the time required to achieve a complete remediation of the Belgian livestock.

The consequences of a bovine viral diarrhoea virus outbreak on herd level production parameters, a case study

Kristof Hermans¹; Jozef Laureyns¹; Geert Opsomer¹; Bonifacius VanRanst¹; Jenne De Koster¹; Mieke Van Eetvelde¹; Sander Moerman¹; Hannes Bogaert¹; Elke Depreester¹; Jan Vandepitte¹; Osvaldo Pascottini¹; Miel Hostens¹

¹Faculty of Veterinary Medicine, Department of Reproduction, Obstetrics and Herd Health., University of Ghent, Merelbeke, Belgium

Objectives: Detecting the circulation of the Bovine Viral Diarrhoea virus (BVDV) in a dairy herd merely based on clinical signs is difficult and often impossible. As a result, recognizing BVD solitary by clinical presentations is a challenge for the bovine practitioner. Proving subclinical damage by BVDV is even more problematic. It has been described earlier that transiently BVDV-infected herds may have higher bulk milk somatic cell counts (SCC) compared with herds considered BVDV-free. The objective of the present case study was to visualize the effect of a confirmed BVDV outbreak on herd level production parameters.

Materials and Methods: The BVDV infection at the herd level was confirmed by screening for BVDV-Ag via a bulk milk sample. In addition, all animals older than three months and not included in the bulk milk sample were blood sampled for BVDV-Ag detection. Blood samples were pooled per 20 animals and RT-PCR was used for virus detection. If the pooled sample turned out to be positive, a BVDV-Ag ELISA test at the animal level was performed. In case an animal was found positive for BVDV antigen, the animal was retested 3 weeks later via a BVDV-Ag ELISA blood test. Fertility data were extracted from the farmer's herd management software. Milk production and somatic cell count (SCC) data were obtained via the 6-weekly milk recording. Three time periods were used in the case study. First, the period nine months preceding the birth of the oldest persistently infected animal detected during screening. The second time period was defined as the period when the detected PI's were on farm. The last period started after the culling of the last PI detected during the screening. Following parameters were calculated per period: average herd milk SCC, average herd milk production, average conception rate and average number of inseminations per pregnant cow.

Results: BVD antigen samples were taken following a BVDV positive abortion on a dairy farm in January 2014. The bulk milk sample of 138 lactating cows turned out to be negative. In total 208 animals were blood sampled for BVDV-Ag detection. Eight animals appeared to be positive. Five animals were confirmed to be a PI and 2 animals turned out to be transiently infected after retesting. One animal died before the second test could be performed. The first PI, detected during screening, was born in the beginning of July 2013. All five PI's were culled at the end of January 2014. The time period prior to the presence of the PI's detected during screening, ran from the first of October 2012 to the end of June 2013. The time period after the culling of the detected PI's ran from the end of January 2014 to the end of October 2014. During the three periods, the average daily milk production per cow decreased from 27.7l to 24l and increased again to 25.5l after the last PI was removed. The average herd SCC raised from 221 to 293 and subsequently declined to 269 once the PI's had been removed. One month prior to the birth of the first detected PI, the average herd SCC was already elevated to 308. Only the month after the birth of the first PI the average herd SCC was higher. The conception rate lowered from 45% to 35% and increased back to 44%. The number of inseminations per pregnant cow was 1.96 in the period prior to the presence of the PI's. It elevated to 2.16 during the BVDV outbreak and dropped to 2.08 after the culling of the PI's.

Conclusions: Via data analysis we showed that the average herd SCC increased, milk production dropped and fertility declined when PI animals were present in a dairy herd. Clearly, not all deteriorations in herd production parameters can be attributed simply to the presence of PI animals. Other factors such as: ration changes, average days in milk and alterations in the management will have an effect on herd production parameters as well. It can be concluded that by combining production and fertility data with BVDV test results, the veterinary practitioner can demonstrate the adverse effects of the BVDV on herd health and production.

BVD

P03-003-045

Identification of a new emerging strain of Border Disease Virus (BDV-8) in Italy using an antigen capture ELISA and real-time PCR.

Claudio Caruso ^{1*} Martina Kahila ² Michael Angelichio ³ Christoph Egli ² Simone Peletto ¹ Francesco Cerutti ¹ Christian Schelp ² Valerie Leathers ³ Pier Luigi Acutis ¹ Loretta Masoero ¹

¹Instituto Zooprofilattico Sperimentale del Piemonte, Turin, Italy, ²IDEXX Switzerland AG, Liebefeld, Switzerland, ³IDEXX Laboratories, Westbrook, United States

Objectives: Recently a Border disease strain (BDV) from a goat and a chamois (*Rupicapra rupicapra*) has been reported in northwestern Italy. Phylogenetic analysis based on the combined 5'-UTR and Npro/partial C genes, showed divergence from known BDV genotypes, revealing the detection of a novel pestivirus group, named BDV genotype 8. Mutations in the 5'-UTR of this emerging strain rises the concerns about the "diagnostic escape" that could occur during routine investigations.

In this study an antigen capture based ELISA kit and a commercial real-time PCR test for BVDV and BDV were used to define the level of detection of the new BDV-8 strain.

Materials and Methods: The IDEXX RealPCR BVDV RNA Test is a real-time PCR test detecting BVDV-1, BVDV-2, BVDV-3 (Hobi-like pestivirus) and BDV. The test works on a modular platform, where a shared RNA Master Mix and a pooled positive control can be used with any RealPCR RNA test. The IDEXX BVDV Ag/Serum Plus Test is an ELISA test based on the detection of BVDV E^{ms} antigen.

A panel of spleen, lung and ear notch samples were prepared from bovine, goat and chamois for real-time PCR analysis. The total sample amount was 8 samples. The samples were collected from animals recently infected with the new BDV-8 and with BDV-3 strains; BVDV-1b, BVDV-1e and BVDV-1f were also included in the study. For ELISA testing, ear notches, spleen and lung infected with BDV-8 and BDV-8 were prepared using the ear notch lysis buffer. The testing followed the manufacturer's instructions.

Results: Both tests showed good sensitivity on all sample types tested. One sample tested negative with the RealPCR BVDV RNA Test, most likely as a consequence of RNA degradation resulting from multiple freeze-thaw cycles. In addition to correct identification of the new BDV-8 strain and the BDV-3 strain, the real-time PCR test was also able to identify BVDV-1b, BVDV-1e and BVDV-1f strains also included in the study.

Both BDV-8 and BDV-3 strains were correctly identified with the BVDV Ag/Serum Plus Test.

Conclusions: This study shows that both ELISA and real-time PCR tests from IDEXX have a broad strain coverage for BVDV and BDV and are able to detect the new BDV-8 strains recently discovered in northwestern Italy.

Demonstrating the efficacy of good biosecurity for BVD control on UK cattle farms

Jude Eze ¹ Selene Huntley ² Katherine Adam ¹ George Gunn ^{1*}

¹Scotland's Rural College, Inverness, ²University of Nottingham, Nottingham, United Kingdom

Objectives: A lack of proof for the efficacy of biosecurity measures to control disease has been identified as a major barrier to the promotion and implementation of biosecurity practices by vets and farmers. The aim of the study was to assess the efficacy of on-farm biosecurity to protect cattle from BVD infection.

Materials and Methods: Blood samples were collected from 24,983 cattle on thirty-nine farms in Scotland and Northern England to assess BVD status. The nine veterinary surgeons for these farms then completed a questionnaire and semi-structured interview on their clients' biosecurity practices. Biosecurity on each farm was classified as poor, fair or good on the basis of these data. Mixed effects models were used to explore the association between biosecurity and BVD status at both farm and animal level while also accounting for covariates. The relative contribution of each of the risk factors to the within-herd seroprevalence and average herd-level BVDV antibody level was quantified after adjusting for the effects of other factors.

Results: Farms where biosecurity practices were classified as good had significantly lower BVD seroprevalence and mean antibody titres than farms which were classified as poor or fair. Animals on farms with poor biosecurity practices are five times more likely to be seropositive for BVD than animals on farms with good biosecurity. On the farms with good biosecurity, mean antibody titres remained low over the four years of the study but increased on the farms with poor or fair biosecurity standards. Cattle on beef farms were twelve times more likely to test seropositive for BVD than cattle on dairy farms, and cattle from large herds were twice as likely to be seropositive when compared to cattle from small herds.

Conclusions: The results provide evidence for the efficacy of biosecurity measures to control BVD infection on cattle farms in the north of Great Britain. The study also indicates that veterinary surgeons' assessments of their clients' biosecurity practices are accurate predictors of the effectiveness of these measures to control disease.

The production impact of an acute BVD outbreak and the economic evaluation of BVD vaccination on a large-scale Hungarian dairy farm – A case study

Laszlo Ozsvari ^{1*} Istvan Jozsi-Toth ² Emese Hanko-Farago ³ Agnes Szabara ¹

¹Dept. of State Veterinary Medicine and Agricultural Economics, Faculty of Veterinary Science, Szent Istvan Univ., Budapest, ²private veterinarian, Hajdúnánás, ³MSD Animal Health, Budapest, Hungary

Objectives: Bovine viral diarrhoea (BVD) virus has a prominent importance among the infectious agents of cattle, due to its direct (production losses) and indirect (trade restrictions) effects on the industry. The average economic loss attributable to BVD was estimated to be € 12.6 per cow in Hungary in 2013. An acute BVD outbreak was estimated to cause € 155k damage for a dairy farm with 1,000 cows, which would suffer € 10k yearly loss due to chronic subclinical infection. The aim of our study was to present the production impact of an acute BVD outbreak and the economic evaluation of BVD vaccination in a large-scale Holstein-Friesian dairy herd.

Materials and Methods: The study was carried out in an averagely 1070-cow Hungarian dairy herd with an average 305-day milk yield of 8,593 kg between 2010 and 2012. In 2010 the number of abortions and calves' culling and mortality rate increased on the farm unexpectedly and significantly. The BVDV infection was confirmed in summer 2011 and in autumn 2011 the BVD vaccination (Bovilis® BVD, MSD-AH) was started in the herd. The major production and animal health parameters on the farm were surveyed between 2010 and 2012. Thus, we compared the production indices influenced by the BVD outbreak (abortion rate, calves' mortality and culling rate) in the year before the vaccination (2010) with those in the year when the entire herd was vaccinated against BVD (2012) in order to conduct the cost-benefit analysis of the BVD vaccination. In the economic analysis the reduction of losses due to the improvement of the BVD-affected production parameters was considered as benefit and the costs of vaccination were taken into account as cost. The average costs and prices of the study period were used in the calculations, where 1 EUR = 300 HUF (value of a 7-day old calf: € 66.67, raising cost of a 6-month old calf: € 426.67, salvage value of a culled calf: € 287, price of BVD vaccine: € 2.61/dose).

Results: The results show that the acute BVD outbreak had a strong detrimental impact on many production and herd health parameters, but after vaccination significant improvement was observed. Between 2010 and 2012 the abortion rate decreased from 4.52% to 1.55%, the rate of newborn calves with hydrocephalus from 0.6% to 0.0%, the mortality rate in suckling calves (up to 60 days of age) from 7.19% to 3.76%, the disposal (mortality and culling) rate in calves aged between 3 and 6 months from 3.49% to 1.92%, the disposal rate in heifers aged between 7 months and 1 year from 2.36% to 0.52%, and the mortality rate in cows from 0.90% to 0.69%, respectively. The number and rate of curative treatments in calves and heifers up to 1 year of age dropped from 427 (57.16%) to 233 (25.75%) cases. In 2012 compared to 2010 the number of digestive treatments in calves and heifers diminished by more than 50% (321 vs. 157 cases), and that of respiratory ones with almost 30% (106 vs. 76 cases).

The annual loss caused by the acute BVD outbreak was calculated to be 24.3 € per cow in 2010. The impact of BVD on milk production was excluded from the loss calculation, because it could largely be influenced by other production factors. In the herd the annual cost of BVD vaccination was € 11,223, but the decrease in the loss owing to an acute BVD outbreak amounted to € 20,240, which means € 9,017 extra profit yearly. The BVD vaccination yielded a profit of 7.7 € per cow in 2012, so as an investment it had 1.8 benefit-cost ratio and 80.35% ROI.

Conclusions: The findings of the case study show that an acute BVD outbreak can bring about significant economic losses, especially in BVD naïve herds. According to the result of the economic analysis, the BVD vaccination was highly profitable, since the benefits stemming from the improved herd production and health parameters exceeded the vaccination cost by far. In herds experiencing substantial losses due to BVDV infection, a vaccination program is worth considering from an economic point of view.

Objectives: This case report will discuss the pitfalls of BVD control management on a Dutch dairy farm where BVD re-entered the farm after several years of being "BVD virus free" and vaccination. Recommendations for improvement are proposed.

Materials and Methods: The farm consisted of a dairy herd containing 170 Holstein Friesian dairy cows with an average milk yield of 7219 kg milk/year with approximately 160 young stock. In summer time cows grazed on pasture from April until October close to another farm. In wintertime, these animals were kept indoors on a ration of grass- and maize silage and minerals.

Vaccination with an inactivated BVD vaccine started in 2008. At that time no information on the BVD status of the herd was available. Vaccination with the inactivated vaccine was performed twice a year according to the label recommendations in 2008 and 2009. Afterwards vaccination with the same vaccine was done only once a year in the adult animals until March 2014. The young stock was vaccinated twice with a 4 week interval. Other vaccinations carried out were monovalent IBR vaccines in cows and multivalent vaccines for pneumonia in young stock. Pneumonia had been a problem in calves for years but the incidence had decreased after improvement of the colostrum management and vaccination. Only a heifer breeding bull was purchased. Measures to monitor the introduction of BVD was done occasionally by blood sampling young stock for antibodies. There was no indication of BVD virus circulation, therefore the farm was considered to be BVD virus free.

Results: In the summer of 2015 pneumonia was diagnosed based on clinical symptoms (coughing, dyspnoea and fever) in calves of 2 to 4 months old. Older calves of 5 to 6 months of age had Trichophyton infection with severe clinical symptoms. Immunosuppression was suspected and diagnostic testing for BVD was performed. Five blood samples from young stock were antibody positive. The whole herd was sampled via bulk milk and individual blood samples for the presence of BVDV. Two persistent infected (PI) animals (born December 2013 and June 2015) were identified and removed. By the age of the oldest PI it was calculated that the BVD circulation took place since the summer of 2013. At the neighbouring farm BVD was also diagnosed in the beginning of 2014. Both PI animals were infected with BVDV type I. All new born calves are tested for BVDV since. So far one new born calf was found to be a PI animal. After removal of the PI's vaccination continued with a new live BVDV vaccine (Bovela, Boehringer Ingelheim) with a 12 month duration of immunity.

Conclusions: On this farm BVD control had been inadequate: no identification and removal of PI and a vaccination interval beyond the 6 month duration of immunity of the inactivated vaccine. To conclude, this case reports emerges the fact that when BVDV control is inadequate all the implemented strategies can be a waste of effort and money. In order to prevent BVDV circulation and (clinical) problems a close collaboration between veterinarians and farmers is needed. Vaccination of all animals from 3 months of age with a live BVD vaccine with a 12 month duration of immunity can help the vet and the farmer with an easier to implement vaccination strategy.

Reproductive outcomes in pregnant ewes experimentally infected with bovine viral diarrhoea virus between days 59 and day 69 of gestation

Caitlin Evans^{1,*}Michael P. Reichel²Frahid Hemmatzadeh¹Peter D. Cockcroft¹

¹School of Animal and Veterinary Science, University of Adelaide, Roseworthy, Australia, ²School of Veterinary Medicine, City University of Hong Kong, Hong Kong, Hong Kong

Objectives: Bovine viral diarrhoea virus (BVDV) is an important and highly prevalent disease of cattle associated with immunosuppression and reproductive losses. Many non-bovine species, including sheep, pigs, camels and deer, have been shown to be susceptible to infection with BVDV, with similar outcomes to those seen in cattle. The aim of this study was to determine what reproductive outcomes would result following the infection of ewes with an Australian BVDV strain between 59 and 69 days gestation.

Materials and Methods: Twenty two ewes, pregnant with 42 foetuses, were inoculated with 2ml of BVDV infected cattle serum at 59-69 days gestation. The remaining 11 ewes, pregnant with 23 foetuses, were not inoculated. Blood samples were taken weekly from all ewes until the week prior to lambing. Pregnancy scanning was undertaken fortnightly, on five occasions. All ewes were fed under the same conditions, although housed separately. Blood samples were obtained from lambs born to infected ewes on the day of birth and weekly until eight weeks of age and an ear notch sample was obtained on the day of birth. Dead, stillborn or aborted foetuses/lambs of infected ewes were submitted for post mortem examination. Serum samples were analysed for BVDV-specific antibodies and BVDV viral antigen by ELISA.

Results: All 22 infected ewes showed seroconversion to BVDV by 49 days post infection. No other signs of infection were observed in any of the ewes. All 11 control ewes remained naïve.

High reproductive losses were observed in the infected ewe flock compared to the control ewes with foetal losses being 83% and 17% respectively. Post mortem examination of aborted, stillborn and dead lambs from infected ewes revealed severe abnormalities including anasarca, pleural effusion, arthrogryposis, severe skull deformities, hydrancephaly and hydronephrosis. One lamb, which subsequently died, presented as a 'hairy shaker' with an abnormal hair coat and muscular tremors. All lambs from infected ewes were of small size and birthweight. One of the 4 surviving lambs was persistently infected with BVDV, surviving until euthanasia at eight weeks of age.

Conclusions: This study has shown that infection of pregnant ewes with BVDV between days 59 and 69 of gestation can result in high foetal losses, many with severe abnormalities. It has also shown that viable persistently BVDV infected lambs can be produced following infection with BVDV between 59 and 69 days gestation. However, the potential for these persistently BVDV infected lambs to infect naïve animals, particularly sheep and cattle, needs to be further studied in order to determine what risk sheep populations may play in the epidemiology of BVDV.

BVD

P03-003-050

Transmission of Bovine Viral Diarrhoea Virus from a persistently infected lamb to naïve sheep

Caitlin Evans¹, Michael P. Reichel², Farhid Hemmatzadeh¹, Peter D. Cockcroft¹

¹School of Animal and Veterinary Science, University of Adelaide, Roseworthy, Australia, ²School of Veterinary Medicine, City University of Hong Kong, Hong Kong, Hong Kong

Objectives: Typically associated with cattle, Bovine viral diarrhoea virus (BVDV) has been shown to cross-species barriers and infect a wide range of ruminant and pseudo-ruminant species including sheep, goats, alpaca and deer. Infection with BVDV can lead to immunosuppression and a wide range of reproductive losses resulting in severe economic losses to farmers. The aim of this study was to determine if naïve sheep would seroconvert to BVDV following co-mingling with a persistently BVDV infected (PI) lamb.

Materials and Methods: Four sentinel BVDV naïve ewes and their five sentinel BVDV naïve lambs were mixed with a flock of recently lambed ewes which had been experimentally infected with BVDV between 59 and 69 days gestation. One viable and confirmed BVDV PI lamb was present in the infected ewe flock. The sentinel animals remained with the infected flock for a period of eight weeks at which time the PI lamb was euthanized. The sentinel animals were blood sampled weekly for the eight weeks following the introduction to the flock and then on two occasions, a fortnight apart, following euthanasia of the PI lamb. Serum samples were analysed for the presence of BVDV-specific antibodies.

Blood samples were taken from the PI lamb from birth until euthanasia at eight weeks of age. Serum samples were analysed for BVDV-specific antibodies and BVDV-specific antigen by ELISA.

An additional control group of 6 BVDV naïve ewes and their 8 lambs were kept in a paddock with a 3m separation from the flock with the PI lamb for a total of 8 weeks. Blood samples were taken from the control group at the end of this period. Serum samples were analysed for BVDV-specific antibodies by ELISA.

Results: Seroconversion to BVDV was observed in one naïve lamb at seven weeks post mixing and then again at eight weeks post mixing. At this eight week time point no other sentinel animals were shown to have sero-converted.

Serum samples taken from the PI lamb indicated the presence of colostral BVDV-specific antibodies at all time points. However, a strong positive antigen result was present on day of birth and again from week 2 to week 8.

All the control animals returned negative test results for BVDV-specific antibodies.

Conclusions: This study has shown that seroconversion in naïve sheep can occur following co-mingling with a BVDV PI lamb. It is thought that the low rate of seroconversion in these naïve animals is due to the inhibitory influence colostral antibodies have on viral excretion.

This study has also demonstrated that no infection occurred in sheep kept in a paddock with a 3m separation gap from the paddock containing the PI lamb.

BVD Foetal Protection Induced By Vaccination In Cattle

Vincent Robles¹, Santiago Casademunt¹, Morgan McArthur²

¹Hipra, Amer (Girona), Spain, ²Free lance consultant, New Berlin, United States

Objectives: The following trial was undertaken to determine if vaccination of sero-negative heifers with a multivalent viral vaccine (HIPRABOVIS®, "Hipra"; Spain) containing a 1a Bovine Viral Diarrhoea (BVD) strain was

able to protect the foetus from infection with a field strain of BVDV. This study was conducted by: ESTENDART LTD, Palmerston North, New-Zealand.

Materials and Methods: Forty eight non-pregnant heifers seronegative to BVDV, Neospora caninum and Enzootic Bovine Leukosis were randomly allocated to two groups of 24. Heifers in one group were vaccinated with a multivalent viral vaccine (HIPRABOVIS®) followed by a booster 21 days later. Heifers in the second group were unvaccinated controls. All 48 heifers were oestrus-synchronized in a CIDR programme then mated using artificial insemination. Ten heifers from each group shown to be pregnant were selected 66 days after insemination and grazed together with 2 persistently infected (PI) calves for the remainder of gestation. All calves born alive were blood sampled at birth prior to suckling colostrum and their BVD status determined by serum neutralization test (SNT) and ELISA Antigen.

Results: Six heifers (1 from the vaccinated group and 5 from the controls) had late abortions (calves at term). All 6 calves were positive for BVD by ELISA Antigen and antibody. Eleven calves were born alive: 7 in the vaccinated group and 4 in the controls. Two of 7 live calves in the vaccinated group were identified as PIs at birth (28.5%) whereas the 4 live calves in controls were all identified as PI animals (100%). When late abortion and PI calf numbers were combined, the protective effect of vaccination with the multivalent viral vaccine (HIPRABOVIS®) was significant compared with the unvaccinated group ($p=0.009$).

Conclusions: The results demonstrate that the use of the 1a BVD strain of a multivalent viral vaccine (HIPRABOVIS®) in seronegative heifers provided significant protection against foetal infection when the herd was exposed to a high level of natural BVD challenge during gestation.

P03-003-052

Impact of administration of two inactivated bovine viral diarrhoea virus (BVDV) vaccines on serological test results in dairy heifers

Riona Sayers¹, Jose M. Lozano², Maria Keane³, Ronan O' Neill⁴, David A. Graham⁵

¹Animal & Biosciences, Teagasc, Moorepark, Fermoy, Co. Cork, ²Virology, Department of Agriculture, Food, and the Marine, Backweston, Celbridge, Co. Kildare, ³Blood Testing Laboratory, Department of Agriculture, Food and the Marine, Model Farm Road, Cork, ⁴Department of Agriculture Food and the Marine, Backweston DAFM Laboratories, Celbridge, Co. Kildare, ⁵Animal Health Ireland, 4-5 The Archways, Carrick-on-Shannon, Co. Leitrim, Ireland

Objectives: BVD vaccines are an integral component of viral control on-farm. Use of BVDV vaccines, however, is a potential confounding factor when interpreting BVD serological results. Previous international studies have examined the impact of vaccination against BVDV on individual animal antibody responses to p80 (non-structural protein 3) and whole virus (WV) antigens, with equivocal results. The aim of the present study was to undertake a controlled trial to investigate the impact of BVD vaccination on the serological status of seronegative dairy heifers using p80 and WV antibody ELISAs.

Materials and Methods: Two inactivated BVD vaccines (Bovidec BVD, Novartis Animal Health and Bovilis BVD, MSD Animal Health) were administered to two treatment groups of 35 yearling maiden heifers. Group sample size was determined to yield a minimum power of 0.08

and a 5% error. A 'before and after' study design was used with animals acting as their own controls. Heifers were assigned to treatment groups based on the vaccine to be administered and balanced by breed (purebred Holstein-Friesian versus crossbred) and body weight. All heifers were blood sampled prior to vaccination. A primary vaccination course (i.e. primary dose and booster at an interval specified by each manufacturer) was administered to each heifer. Heifers were re-sampled at day 14, 28, 60, and 180 post-vaccination. Samples were tested using seven commercially available BVD ELISA kits. Of these, five detected antibodies against p80 antigen and two detected WV responses.

Descriptive data were coded and analysed in Excel (MS Office 2010). ELISA results were categorised as positive or negative. Doubtful results were also classified as negative. Statistical analyses were completed using Stata version 12 (StataCorp, US). Differences across treatment groups and between ELISA kits over time were investigated general estimating equations. A binomial distribution, logit link function, and an autoregressive correlation were assumed. Results were reported as exponentiated coefficients (odds ratios).

Results: All 70 heifers tested seronegative pre-vaccination on each of the ELISA tests used with the exception of a single test kit (a confirmatory WVELISA) which recorded eight seropositive individuals. By day 14 post-vaccination, all test kits yielded seropositive individuals amongst the 70 tested in both treatment groups (range 7-36, p80 kits; range 65-68, WV kits). By day 180 post-vaccination, the number of seropositive heifers, and the likelihood of recording a seropositive result, decreased significantly ($P<0.001$) across all test kits (range 4-27, p80; range 13-26, WV). When all test results were considered, heifers vaccinated with Bovidec were almost three times more likely ($OR=2.9$; $P<0.001$) to record a seropositive result than those vaccinated with Bovilis over the duration of the study. The odds ratio of recording a positive result post-vaccination compared to pre-vaccination decreased from 274:1 at day 14 to 23:1 at day 180 ($P<0.001$) for Bovidec-vaccinated heifers and from 136:1 at day 14 to 24:1 at day 180 for Bovilis-vaccinated herds.

Conclusions: Administration of inactivated BVD vaccines impacts on interpretation of individual BVD serological results. The extent of confounding, however, varies significantly across vaccine brand, ELISA test kit, and the date of sampling post-vaccination. In general, use of p80 kits will facilitate interpretation of ELISA results in vaccinated herds. Based on the results of this study, it may be possible to identify a combination of inactivated vaccine and p80 ELISA which would allow use of BVD serological surveillance in a vaccinated population.

Serological evidence of HoBi-like virus circulation in Argentinean water buffaloes

Andrea Pecora¹, Maria S. Perez Aguirreburualde¹, Dario A. Malacari¹, Osvaldo Zabal¹, Juan Sala², Sergio G. Caspe², Fernando Bauermann³, Julia Ridpath³, Maria J. Dus Santos¹

¹CICVyA, INTA, Buenos Aires, ²EEA Mercedes, INTA, Corrientes, Argentina, ³USDA, Ames, Iowa, United States

Objectives: The aim of this work was to determine and compare the antibody levels against BVDV-1, BVDV-2 and HoBi-like virus in non-vaccinated water buffaloes from three provinces in the Northeast region of Argentina.

Materials and Methods: Mediterranean and Murrah Water buffaloes (n = 130) were sampled from 12 extensive breeding farms across Corrientes, Chaco and Formosa provinces in Argentina. Blood samples from each animal were aseptically collected from the jugular vein in sterile Vacutainer using separate needles. [FB1] Sera were obtained after centrifugation and the inactivation was performed at 56°C for 30 minutes.

Virus neutralization assays were performed for each serum, using 96-well plates, MDBK cells and 100 TCID₅₀ of cytopathic BVDV-1-Singer, BVDV-2-VS253 and a HoBi-like virus isolate. Two-fold serial dilutions were performed in the serum samples to determine the neutralizing antibody titers against BVDV-1, BVDV-2 and HoBi-like virus. The neutralizing antibody titers were expressed as the reciprocal of the highest dilution that neutralized viral infectivity. Spearman-Kärber titers were calculated to analyze the results.

Results: While eighty-eight water buffaloes were seronegative to the three pestiviruses, 53% of the seropositive animals (n=22) contained significant higher levels of neutralizing antibodies against HoBi-like virus than to BVDV-1a or BVDV-2. About 40% of the seropositive animals showed significant higher levels to BVDV-1 in comparison to BVDV-2 and HoBi-like virus and the rest of them (7%) showed similar neutralizing antibody levels against BVDV-1 and HoBi-like virus.

All the animals that showed higher neutralizing antibody titers against HoBi-like virus belonged to farms located in Corrientes Province, border with Brazil. On the other hand, water buffaloes from Formosa and Chaco provinces were seronegative against the three strains or showed higher levels of neutralizing antibodies against BVDV-1.

Conclusions: The circulation of BVDV-1 in argentinean water buffaloes has been previously reported (Craig et al, 2015). However, in this work, we found for the first time serological evidence of HoBi-like virus circulation in water buffalo livestock in Argentina. The provinces involved in this study are located near Brazil, where several reports of HoBi-like virus in cattle herds were disclosed.

Further work should be performed to isolate the local HoBi-like virus and to determine its pathogenicity. Also, it should be determined if this virus is also affecting cattle from the analyzed region.

Prevalence of bovine viral diarrhoea virus infection in Hokkaido, Japan; epidemiological analyses based on the viral genotype

Motoshi Tajima¹ Atsuko Nitta¹ Mari Sawada¹ Hokuto Nakamura¹ Hiromichi Ohtsuka¹

¹School of Veterinary Medicine, Rakuno Gakuen University, Ebetsu 069-8501, Hokkaido, Japan

Objectives: Persistently infected (PI) cattle with bovine viral diarrhoea virus (BVDV) spread a lot of virus particles within the herd. When the fetus infect with BVDV in uterus at some pregnancy period, PI calf is produced at the results of immunotolerance. PI cow is the central issue for the control of BVDV as the source of infection. The estimation of the prevalence status of BVDV is important for the control of BVDV infection. In the present study, we investigated the virus genotypes of PIs detected in Hokkaido, Japan, during 8 months period, and analyzed epidemiologically.

Materials and Methods: From November 2014 to July 2015, approximately 26,000 cattle were examined for BVDV infection in Veterinary Teaching Hospital of Rakuno Gakuen University, and 124 PIs were detected. Viral gene was detected from their sera by reverse transcription polymerase chain reaction (RT-PCR) using specific universal primers for BVDV gene. For the classification of the genotype as BVDV1 or BVDV2, RT-PCR using genotype specific primers was utilized. The relationships between genotypes and species, gender, age, occurrence place, or infected place were estimated.

Results: The ratio of BVDV1 and BVDV2 was 7 (88 PIs): 3 (36 PIs). The deviation of genotype distribution pattern was almost the same with previous report in Japan. Only 3 PIs indicated clinical symptoms such as pneumonia or diarrhea. The virus genotype distribution in female and male PIs was almost the same in each gender. There was no different distribution of genotype in three species, Holstein, Japanese Black and F1, and also not in different age. In occurrence place of PI, BVDV2 significantly dominant (p<0.05) area was recognized. The obvious cause of this dominance was not clear.

Conclusions: The deviation of prevalent genotype in BVDV detected during short period (8months) was almost the same with previous report. This suggested that vaccination control is not effective for BVDV PI over a decade.

Serological and molecular confirmation of bovine viral diarrhoea virus subgenotype 1b in yearling buffaloes (Bubalus bubalis) from Northeastern Brazil

Sonália F. Paixão^{1,2} Juliana T. T. Fritzen² Sarah E. I. Crespo² Selwyn Headley² Alice F. Alfieri² Amauri A. Alfieri²

¹Department of Animal research, Instituto Federal de Educação, Ciência e Tecnologia, São Luis, ²Department of Veterinary Preventive Medicine, Universidade Estadual de Londrina, Londrina, Brazil

Objectives: Bovine viral diarrhoea (BVD) is an infectious disease that affects cattle of all ages, that is caused by bovine viral diarrhoea virus (BVDV), and occurs worldwide. The susceptibility of buffaloes (Bubalus bubalis) to this virus was demonstrated by serology and molecular techniques. Although there are serological demonstrations of BVDV in buffaloes from Brazil, there is no molecular confirmation of the viral subgenotype circulating in buffalo herds. The objectives of this study were to describe the serological prevalence of BVDV-1 in buffaloes and determine the molecular subtype circulating in herds from Maranhão state, Northeastern Brazil.

Materials and Methods: This study was performed in two buffalo farms (A, n=316; B, n=387), located in the state of Maranhão, Northeastern Brazil. Buffaloes at these herds were reared in close proximity and had sporadic contact with cattle. Serum samples (n=223) from asymptomatic yearlings buffaloes were collected (herd A, n=105; herd B, n=118). These samples were submitted to the BVDV-1a (Singer strain) virus neutralization (VN) technique according to OIE. To determine which genotype of BVDV was circulating in each herd, the nucleic acid of BVDV was extracted from serum samples and used in RT-PCR assays designed to amplify the 5'UTR region of BVDV by using the 324/326 primers. Positive and negative controls were included in each RT-PCR assay. Selected positive serum samples were then sequenced and the derived amplicon analyzed phylogenetically to determine the relationship with similar isolates.

Results: Serological analyses revealed that 40% (42/105) of the yearlings at herd A were seropositive to BVDV-1, with seropositivity being 52.5% (62/118) at herd B. The presence of anti-BVDV antibodies at these two buffalo herds confirmed the circulation of this virus at these locations. However, from the 62 serum samples (herd A, n=52; B, n=10) that were subjected to the BVDV RT-PCR assay, 17.7% (herd A, n=6; B, n=5) were viremic at that time and were considered as being transiently infected. Additionally, sequencing and phylogenetic analysis demonstrated that two isolates clustered with other strains of the BVDV 1b subgenotype.

Conclusions: The results of the serological assays demonstrated that a large proportion of buffalos at both herds were infected by BVDV-1. Additionally, the amplifying and sequencing of BVDV from two seropositive animals confirmed that these were infected by this virus, while phylogenetic relationship revealed that these yearling buffalos were infected by BVDV 1b subgenotype. Additionally, the presence of the BVDV in these buffalos was probably due to the close contact with cattle. Although buffalos are rustic and considered resistant to several diseases, in this case the buffalos were susceptible to infection by BVDV.

The use of Clinical Audit to support structured communication and diagnostic protocols in BVDV control across a national veterinary practice

Jon Parsons¹, Rebecca Adamczyk¹, Ian Nanjiani¹, Jon Mouncey¹

¹Westpoint Veterinary Group, Sevenoaks, United Kingdom

Objectives: A farm's Bovine Viral Diarrhoea Virus (BVDV) status can be clearly determined by applying systematic diagnostic protocols as part of (or outside) accredited health scheme protocols, allowing the targeted implementation of appropriate disease control measures. The impact of a structured communication and engagement campaign on farm engagement with BVD control was assessed in a large veterinary practice using paired clinical audits.

Materials and Methods: A clinical audit of farm/herd BVD status was conducted in August 2014, across a multi-site national farm animal veterinary group in dairy farms in advance of a structured communications and engagement campaign of regional meetings, internal webinars and newsletters/leaflets to farmers over a 3 month period in Spring 2015. The clinical audit was repeated 16 months later. Farm BVDV status was assigned in line with health scheme definitions (CHECs protocols), and the level of engagement in BVDV control was defined by the level of engagement with systematic BVDV diagnostics used (members of health scheme; structured testing outside of health scheme; no/sporadic testing). The proportion of farms engaged in health schemes and structured testing was compared, as were changes in herd status for BVDV.

Results: The initial clinical audit revealed inconsistencies in the way vets were classifying farms BVD status, though these could easily be rationalised by retrospectively applying health scheme definitions of farm status. The second clinical audit will be conducted in the winter of 2015/2016 using health scheme definitions of BVDV status. Comparisons between the two audits will include changes in the number of farms engaged with structured BVDV testing/control (either within our

outside health schemes), changes in the health status of farms (both within and outside health schemes), and the results will determine the value of the structured communication and engagement campaign in driving engagement with BVDV disease control on-farm.

Conclusions: This study does show the benefit and importance of working alongside CHECs recommendations and health scheme protocols. Standardising farm BVDV disease status classification improved communication/focus between participating veterinarians by establishing common language & definitions. Engaging farmers in structured discussions on BVDV control is likely to improve understanding of the disease impact, and buy-in to disease control. Clinical audit is a valuable tool in monitoring disease control, allowing focussed targeting of problem farms.

Comments: The authors are grateful for the support of Westpoint Veterinary Group's Infectious Disease Working Group, the Clinical Governance, Marketing and Knowledge Transfer Groups and Biobest Laboratories for their input into the conduct of this work.

P03-003-057

Relationship between initial BVD ELISA and real time RTPCR test values for ear tissue and the outcome of confirmatory testing of blood samples.

David Graham¹, Ronan O'Neill², Clare Gallagher², Padraig O'Sullivan³

¹Animal Health Ireland, Carrick on Shannon, ²Virology, Central Veterinary Research Laboratory, Dublin, ³Irish Cattle Breeding Federation, Bandon, Ireland

Objectives: Currently all Irish calves are tested for BVD virus as part of a national eradication programme. After an initial positive or inconclusive result, a confirmatory test to differentiate between transiently infected (TI) and persistently infected (PI) animals may be performed on blood samples submitted to the National Reference Laboratory (NRL).

It was hypothesized that the test value associated with an initial positive or inconclusive result for an ear notch sample tested by ELISA or real time (rt)RTPCR, may be used to predict the outcome of a confirmatory test. The current study was undertaken to test this hypothesis.

Materials and Methods: Test results were retrieved from the programme database (managed by the Irish Cattle Breeding Federation) for all calves with an initial inconclusive or positive result on a tissue sample collected from the ear during using a modified identity tag that had also been subjected to a confirmatory test by the NRL. Calves were excluded if the inter-sample interval was <21 days.

For samples where the initial test was conducted by ELISA, the initial test values (S-N) were assigned to a series of incremental categories and the number and percentage of animals re-testing with inconclusive, positive or negative results determined for each category. Based on these numbers, the likelihood ratio (number positive: number negative) of animals in each category giving a positive re-test result was determined.

Data for samples where the initial test was conducted by rtRTPCR were analysed in a similar way.

Results: Results for a total of 21,181 calves met the criteria for inclusion. Of these, 17,498 and 3,683 had been tested initially by ELISA and rtRTPCR respectively. Results for the former indicated that the lowest likelihood ratios (0.20) were associated with those calves which had an initial inconclusive (0.2 >S-N ≤0.3), or a weakly positive ((0.3 >S-N

≤0.4) ELISA result. The ratio increased with S-N values ($r^2= 0.967$, $y = 3.1676x^{2.513}$). Values of 1.0 and above had consistently high likelihood ratios (4.0-76.5). A similar pattern was evident when rtRTPCR results were analysed, with Ct values on initial testing of >30 being associated with low likelihood ratios (≤0.2), whereas those with lower Ct values had a high likelihood of being PI, with ratios in the range 3.0 to 27.8.

Conclusions: The initial test value obtained by ELISA or RT-PCR on ear punch can be used as an indicator of the likelihood that the calf will be positive on re-test (and therefore PI). This information can be used to assist decisions as to whether or to re-sample a given calf and help ensure the prompt removal of PI calves.

Do Too Many Tests Spoil the Eradication of Bovine Viral Diarrhoea?

Andrew Duncan^{1,2}George Gunn²Roger Humphry²

¹Inverness College UHI, ²SRUC Epi Unit, Inverness, United Kingdom

Objectives: Globally, the eradication of bovine viral diarrhoea is still in its infancy but eradication has been, or is being, adopted by several countries. Lessons can be learnt from this progress in two main ways. The first is by making comparisons between countries to assess best practice and the second is by pooling published results from different countries to get greater statistical power in asking scientific questions of the data. We set out to evaluate whether a relationship between published BVDV test results could be created. We also examined the time taken to retest following an initial antibody BVDV test in the Scottish eradication scheme.

Materials and Methods: Differences in the way in which BVDV is measured are not just a barrier to academic progress, but also may affect the progress within an eradication scheme itself.

In an attempt to establish relationships between published BVDV test results we carried out a systematic literature review following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines.

We tested the time taken to retest based type of initial antibody test using a one-sided proportion test. The samples were split by initial test type (blood or milk) and the proportions of those retesting within 90 days following an initial not negative result were examined.

Results: We report the results of the systematic review, providing a summary of papers where there is potential cross-calibration and a summary of the obstacles preventing such data-pooling. The main barriers came in the form of vaccination, test variety and the way test results were reported.

Graphical and statistical evidence from survival analysis show that within the Scottish BVDV eradication scheme, holdings retest quicker from a not negative antibody blood test compared to an initial not negative antibody milk test.

Conclusions: When an eradication scheme is being designed the tests and testing methods should be designed so the scheme does not discombobulate itself. Academic researchers can assist with this by considering how comparable their results are with existing test results.

P03-003-059

Control of bovine viral diarrhoea virus (BVDV) in Flores and Corvo Islands from the Azores archipelago

João V. Corvelo¹Sandra Benevides²Carlos Pinto³

¹Direção Regional da Agricultura, Serviços de Desenvolvimento Agrário das Flores e Corvo, Azores, ²Direção Regional da Agricultura, Laboratório Regional de Veterinária, Angra do Heroísmo, ³Direção Regional da Agricultura, Serviços de Desenvolvimento Agrário De São Miguel, Ponta Delgada, Portugal

Objectives: This project aims control and eradicate BVDV in cattle population from Flores and Corvo Islands, in the Azores through the screening and culling of persistently infected animals (PI). And still continue encourage the measures of biosecurity, the effective vaccination to prevent fetal infection in heifers and beef cattle and the consequences of BVDV infections in herds.

Materials and Methods: The Flores and Corvo Islands belong to the western group of the Azores archipelago. There are about 5000 bovines distributed by 60 herds from which 30 are dairy herds. In this survey all cattle from dairy herds were tested for the presence of antibodies against BVDV and for the presence of BVDV. The screening was performed with individual serum samples using the enzyme linked immunosorbent assay (ELISA) antibody test and pools of serum and EDTA blood samples using Real Time Polymerase Chain Reaction (RT-qPCR).

Results: Seroprevalence and prevalence of BVDV was determined in 30 dairy herds, testing 227 cattle from Flores Island and 17 from Corvo Island, during October 2015. All the dairy herds were under official sanitation, most of them presenting fertility problems. It was not detected any transitory infected animal with BVDV and any PI animals. But the seroprevalence of BVDV between herds was 100% in Corvo Island and 84.0% in Flores Island. The seroprevalence of BVDV between animals was 46.5% and 82.35%, respectively.

Conclusions: This study was the first step to control and eradicate the BVDV in cattle from these two islands. Given the high rate of herds and animals affected by BVDV, it is essential to take action in herds, do an epidemiological survey to find the cause of this seroprevalence, slaughtering PI animals, and implementing measures to prevent the dissemination of the virus in cattle population.

BVD

P03-003-060

Retrospective study of BVD 3 in Brazilian cattle herds

Eliana De Stefano¹Líria H. Okuda¹Edviges M. Pituco¹Adriana N. Romaldini¹Cláudia P. Ribeiro¹Ana L. Pini¹

¹Laboratory of Bovine viruses, Instituto Biológico, São Paulo/São Paulo, Brazil

Objectives: In 2004 Bovine Viral Diarrhoea Virus 3 (BVDV 3) was detected from a batch of FBS and since then, the virus has been repeatedly isolated from batches of FBS either from animals with respiratory signs or aborted fetus. BVDV belongs to the family Flaviviridae genus Pestivirus and is one of the most important pathogens responsible for reproductive fails and some cases are associated with respiratory and neurological

disorders. The aim of this study was evaluate the frequency of BVDV3 in Brazilian herds with neurological signs, reproductive fails or diarrhea from January 2005 to December 2014.

Materials and Methods: The material comprised samples received at laboratory of bovine viruses of Instituto Biológico of São Paulo State. They were from north, middle east, southeast and south regions of Brazil. A total of 246 samples were analyzed of which, 226 were batches of FBS, 174 were tissues from animals with neurological signs, respiratory or diarrhea sings and 18 aborted fetuses. The samples were submitted to RT-qPC using TaqMan system. Positive samples were subjected to sequencing using primers of 5'UTR region odified gene.

Results: The RT-qPCR detected BVDV in 34 FBS and 9 tissues (CNS, lung, faeces), totalizing 43 positive samples. BVDV was not found in fetus and diarrhea symptoms demonstrating other causes of abortion and gastroenteritis. From positive samples, 20 were submitted to sequencing and were identified genotype 3 in 16 samples (14 in FBS and 2 in tissues) and genotype 1 in 5 FBS, with approximately 95 to 99% of identity. The BVDV 3 was detected in Paraná (1), Sao Paulo (14) and Minas Gerais (1) States. On the other hand BVDV 1 was identified in Sao Paulo (4) and Parana (1) states.

Conclusions: The study highlights the importance of phylogenetic characterization of BVDV and demonstrate the circulation of BVDV 3 in Brazil, mainly in state of Sao Paulo and also the importance of monitoring batches of FBS.

Results: The data do not present normal distribution, so the statistic differences between medians of Abs (Log2) were determined by Kruskal-Wallis test. The correlation between Abs titers and age was performed by Spearman test. The Mann-Whitney test was used to evaluate the relationship between age and seropositive frequencies for p80. Heifers were seropositive (100%) of M1 to M13. Median Abs titers (Log2) found the M1 to M13, respectively, were 8.3; 7.3; 6.3; 5.3; 6.3; 5.3; 6.3; 6.3; 5.3; 6.3, 6.3 and 6.3. The Abs titers of obtained in M1 were different from the M2-M13 (P=0.001); M2 was statistic different M4 (P = 0.01) and M6 (0.05). The frequencies (%) seropositive heifers for p80 M1 to M13, respectively, were 24.7; 18.2; 10.8; 11.8; 73.3; 73.8; 72.4; 58.1; 45.9; 48.4; 46.2; 47.1 e 61.0. It was possible to verify correlation between Abs titers and ages, observing higher titers in younger heifers (P=0.001). Positive correlation was also observed for the seropositive rate in heifers with p80 from the M5 (P=0.001).

Conclusions: It is possible to conclude that maternal Abs titers showed gradual decline during the first five months of life, which coincided with the increase of seropositive heifers frequency for p80. The inversion occurred between the maternal Abs titers and increased Abs to p80 which indicates that the moment of greatest risk for natural infections caused by BVDV. It is believed that the immunosuppression caused by BVDV can be a risk factor for Respiratory Disease, Anapalsmosis and Babesiosis.

Acknowledgements: Zoetis, Brazil.

Interface Between Maternal Antibodies And Natural Challenge For Bovine Viral Diarrhea Virus (Bvdv) In Dairy Heifers

Camila C. Baccili¹Natália M. Sobreira²Sérgio Soriano³Bruno T. Silva¹Edviges M. Pituco⁴Cláudia P. Ribeiro⁴Aline G. A. Guilloux⁵Viviani Gomes^{1,*}

¹Internal Medicine, University of São Paulo, São Paulo, ²Colorado Farm, Araras, Brazil, ³undefined, Colorado Farm, Araras, ⁴Bovine viruses laboratory, Biological Institute, ⁵University of São Paulo, São Paulo, Brazil

Objectives: The objective of this research was to evaluate the interface between passive and active immunity for Bovine Viral Diarrhea Virus (BVDV) in Holstein black and white females in the first 13 months of age.

Materials and Methods: Serum samples were analyzed from 572 heifers by serum neutralization (SN) and indirect enzyme immunoassay (Elisa) for the p80 protein (BVD/BD p80/125 protein). The immunization program adopted was initiated with 1st milking colostrum intake (lg ≥ 50mg/mL), 4-6L in the first 12 hours of life, from cows vaccinated with the polyvalent vaccine Cattle Master Gold FP5+L5[®] (Zoetis, Brazil), which contains inactivated BVDV-1 (strain 5960) isolated of Iowa (USA) and BVDV-2 (strain 53637) an isolated of Ontario (USA). According to records of the farm, calves received the first dose of vaccine between three to ten months of age and a booster after 30 days, then, females were included in biannual vaccination schedule. Heifers were classified according to their age by the month of life: M1 (n=89), M2 (n=76), M3 (n=67), M4 (n=50), M5 (n=58) M6 (n=40), M7 (n=57), M8 (n= 30), M9 (n=35), M10 (n=28), M11 (n=13), M12 (n=16) and M13 (n=17). Serum samples were collected for specific antibodies (Abs) detection for BVDV by SN and Elisa (SERELISA BVD p80 Ab Mono blocking kit[®], Synbiotic).

Camelids

P02-002-212

Study on important viral infections in New World Camelids in Austria

Thomas Wittek¹* Bianca Lambacher¹ Michaela Eichinger² Sonja Franz¹ Anna Stanitznig¹

¹Vetmeduni Vienna, University Clinic for Ruminants, Vienna, ²Austrian Agency for Health and Food Safety, Mödling, Austria

Objectives: The population of New World Camelids (NWCs) in Austria is now estimated to about 4000 to 6000. In a substantial number of herds in Austria the camelids are kept together with ruminants or they have indirect contact by being kept on the same pastures. NWCs are susceptible to a number of viral pathogens which are important for ruminants such as bovine herpes virus 1 (BHV-1), bovine viral diarrhoea virus (BVDV), Schmallenberg virus (SBV), bluetongue virus (BTV). The objective of the study was to assess the role of NWCs as potential carrier of certain viral pathogens and to estimate the potential infectious risk for ruminants.

Materials and Methods: The total number of NWCs in the study was estimated to be approximately 10% of the total population of NWCs in Austria. All federal states of Austria have been included in the study. The farms have been visited, management and husbandry evaluated, animals have been clinically examined and blood samples have been taken from the jugular vein. Further it has been recorded if the animals were born in Austria or imported from abroad. In the present study 447 serum samples from 186 llamas and 261 alpacas have been collected which were representative for entire Austria. The samples were examined for BHV-1 antibodies (Ab), for BVDV Ab and antigen (Ag), for SBV Ab, and for BTV Ab. Commercially available tests were modified and partially validated for NWC.

Results: From March to July 2014 78 farms have been visited and 447 animals older than one year have been examined and sampled; 186 of these animals were llamas and 261 alpacas. One sample was positive for BHV-1 Ab (0.2 %), one was positive for BVDV antibodies (0.2 %), zero were positive for BVDV Ag (0 %), 323 were positive for SBV Ab (67.7 %) and 53 samples were positive for BTV Ab (11.8 %). Age of the animals did not influence the frequency of AB detection. Differences between several regions of Austria have been found in BTV and SBV AB frequency which can be most likely explained by different geologic conditions (alpine mountains versus lowland areas). Additionally, tendencies have been identified that llamas show different infection pattern in comparison to alpacas. Data on prevalence of SBV, BTV, BVDV, and BHV-1 in NWCs had not been determined for Austria yet. The present study seems to be the first study, which describes the seroprevalence of these viruses in Austrian llamas and alpaca population.

Conclusions: Conducting such a seroprevalence study was important to assess the role of NWCs as potential carrier of viral pathogens and to estimate the potential infectious risk for farm animals especially ruminants. In summary it can be said that the two viruses BVDV and BHV-1 play currently a minor role in Austria. A high number of NWC were infected with BTV and SBV and have been found seropositive. It can be suggested that NWCs may act as a reservoir for BTV and SBV and may play an important role in its transmission. Therefore continuous monitoring of the population is necessary.

P02-002-213

Transabdominal Ultrasound in South American Camelids: methods and physiological findings

Cassandra Eibl¹* Sonja Franz¹

¹Clinic for Ruminants, University of Veterinary Medicine Vienna, 1210 Vienna, Austria

Objectives: There is a lack of information dealing with the method of abdominal ultrasonography in South American Camelids (SACs) and also the normal sonographic appearance of abdominal organs, a fact that seems to be basic prerequisite for the use of ultrasonography as a diagnostic tool in diseased animals. Only a few case reports describe abdominal diseases and their clinical pathology, using ultrasound as a diagnostic aid. Therefore the aim of this study was to establish an ultrasound method for examining different abdominal organs in SACs and to describe their normal ultrasonographic appearance.

Materials and Methods: The study was realised on private alpaca and llama farms in Austria. Parts of the abdomen of 100 clinically healthy adult llamas and alpacas (over 1 year of age) were examined ultrasonographically. For ultrasonographic examination the fleece of the animal was parted at the region of interest at the base of the hair and soaked with alcohol, before placing the probe on the skin. A 6.6 MHz convex transducer was used. The abdomen was scanned on the left and right side and in the ventral caudal region with attention to the kidneys, the urinary bladder, the spleen, the compartments, the duodenum, and the liver. Sonographic appearance of these organs and best location for their sonographic identification were described.

Results: Performing ultrasonography using only alcohol as contact medium between probe and skin without clipping the hair was performed successfully in all animals. On the left side of the abdomen the left kidney was best seen dorsally in the left paralumbar fossa between the 4th and 7th transverse process of the caudal lumbar vertebra. The hyperechoic renal pelvis, the hilus of kidney and the hypoechoic renal parenchyma could be visualised sonographically. The ureter was not visible. The basis of the spleen, with its homogeneous and echoic pattern displayed anterior to the left kidney and showed a typical L-form. Anechoic vessels inside the spleen and a thin echoic capsule surrounding the spleen tissue could be detected. Adjacent to the spleen the wall of the compartment 1 displayed as an echoic band and was localised cranial to the spleen. On the right side of the abdomen the liver was best viewed between the 9th, 10th and 11th intercostal space. The liver showed a hypoechoic, homogeneous tissue pattern with anechoic vessels inside. In the 10th intercostal space an ultrasonographic window allowed visualisation of parts of the right liver lobe, the echoic wall of the dorsal portion of the compartment 3 and parts of the duodenum. The right kidney was visible by positioning the probe in the right paralumbar fossa behind the last rib. For the visualisation of the urinary bladder the transducer was placed in the caudoventral abdomen in the area of the teats. The urinary bladder could be seen only when it was filled with urine.

Conclusions: Transcutaneous abdominal ultrasonography enables a safe technique for the examination of different abdominal organs in SACs. The animals well tolerated the procedure. The use of alcohol as contact medium between probe and skin and the abdication of clipping the hair ruled out to be a suitable technique in SACs and therefore can be recommended. The results of this study show that ultrasonography can be expected to be of great practical diagnostic value in patients suffering from abdominal diseases.

Dexmedetomidine and tiletamine-zolazepam anesthesia in alpacas

Reza Seddighi¹Agricola Odoi²Tom Doherty^{1,*}

¹Large Animal Clinical Sciences, ²Dept of Biomedical and diagnostic Sciences, University of TN, Knoxville, United States

Objectives: To evaluate the effect of intramuscularly administered tiletamine-zolazepam (TZ) with either dexmedetomidine or saline, on immobility, selected cardiorespiratory variables, and recovery quality in alpacas.

Materials and Methods: Five adult, male alpacas were studied using a Latin square design. Each alpaca was given TZ (2 mg/kg) combined with either dexmedetomidine at 5 µg/kg (D5), 10 µg/kg (D10), 15 µg/kg (D15), or 20 µg/kg (D20), or saline (C), intramuscularly at 1-week intervals. The doses of TZ and dexmedetomidine were prepared separately, combined in a syringe, and injected into a semitendinosus or semimembranosus muscle. Immobility, defined as the lack of motor response to claw clamping, was assessed, and characteristics of anesthesia, recovery, and selected cardiorespiratory variables were recorded.

Results: Duration of immobility was longest for animals in treatment D15 (30.9±5.9 minutes) and D20 (40.8±5.9 minutes). Duration of lateral recumbency was significantly longer when animals were given dexmedetomidine. The longest time (81.3±10.4 minutes) to standing was observed in treatment D20. Four control animals moved in response to claw clamping at the five minute time point. Heart rate decreased in all dexmedetomidine treatment groups in comparison with the baseline values. The PaO₂ values for treatments D10, D15, and D20 were significantly less than the control treatment during the first 15 minutes (P<0.05). Three alpacas in the control treatment and one in D5 exhibited muscle stiffness during recovery and had multiple efforts to regain the sternal position; all other recoveries were graded as excellent.

Conclusions: Administration of TZ (2mg/kg) IM without the addition of dexmedetomidine allowed all alpacas to be placed in lateral recumbency, but only one alpaca exhibited a lack of motor response to claw clamping. Dexmedetomidine at 5 µg/kg with TZ (2 mg/kg), induced only a brief period of immobilization; however, doses of 10, 15 and 20 µg/kg increased the duration of immobility.

Establishment of biochemical and haematological reference values for alpacas (Lama pacos) reared in Europe

Mathilde Hoolbecq^{1,*}Isabelle Lagrange²Mireille Dubord²Bodovoahangy Andriatiana ²Guillaume Belbis¹Sylvain Bellier²

¹Hospitalisation Grands Animaux, ²Biopôle, Ecole nationale vétérinaire d'Alfort, Maisons Alfort, France

Objectives: Small camelids are increasingly encountered in European veterinarian practices. The laboratory tests represent an important tool in the diagnosis of alpaca's diseases. Haematological and biochemical reference values can be influenced by climate, geographical areas or

nutrition. However, all data available were obtained from alpacas reared in America, and no data were available regarding alpacas reared in European conditions.

The aims of this study were to establish reference intervals for biochemical and haematological tests in alpacas, to compare results of automated and manual haematocrit, and to describe normal morphology of blood cells.

Materials and Methods: Blood was collected from clinically healthy female and male adult alpacas (Lama pacos) from the only herd close enough from the veterinary school and its laboratory to ensure proper conservation of samples before analyses.

Blood samples (n = 44) underwent full cell blood count analysis using the Sysmex XT 2000iv analyser. Microhaematocrit measures were also performed manually, using a microhaematocrit centrifuge (centrifugation for 5 minutes at 11000 rpm). Blood smears, stained with May Grunwald Giemsa (MGG) and brilliant Cresyl blue (BCB) staining, were checked for manual differential WBC counts, platelet estimates, and morphologic examination of blood cells.

Blood samples (n=43) were assessed for urea nitrogen, creatinine, and glucose concentrations, and for aspartate transferase (AST), creatine kinase (CK) and γ-glutamyl-transferase (GGT) activities using Vitalab Selectra XL analyser (Vital Scientific).

Reference intervals were established using robust and parametric methods after identification of outlier values and transformation of data that didn't have a normal distribution into a normal one by using a Box-Cox transformation.

Results: Biochemical reference intervals for alpacas reared in France were quite similar to those reported previously on alpacas reared in America, except for higher CK-related results and, to a lesser extent, for AST.

Haematological reference intervals for alpacas, using automated analyser, were also similar to those reported previously, except for lower platelets-related and haematocrit-related results. Correlation between automated and manual microhaematocrit was weak, with a systematic undervaluation of haematocrit when performing automated test in comparison with manual microhaematocrit.

Blood smears results were also consistent with previous description of alpaca's blood cells morphology. However, no Cabot rings were observed. Moreover, small basophilic dots were encountered under the membrane of red blood cells, both with MGG and BCB staining.

Conclusions: This is the first European work published concerning biochemical and haematological reference values for alpacas. Our results will be useful guides for interpreting test results ; however, more herds need to be involved in a second part of this work in order to limit herd bias. Moreover, haematocrit values obtained with automated test should be interpreted cautiously, and manual microhaematocrit should be performed systematically.

Finally, as far as we know, this is the first description of basophilic punctuations in alpaca's red blood cells with MGG and BCB staining; further studies are needed to explain the origin of these punctuations.

High prevalence of "Candidatus Mycoplasma haemolamae" in Austrian llamas and alpacas

Sonja Franz^{1,*}Spergser Joachim²Bianca Lambacher¹Anna Stanitznig¹Thomas Wittek¹

¹Clinic for Ruminants, University of Veterinary Medicine Vienna,
²Institute for Microbiology, University of Veterinary Medicine Vienna,
 1210 Vienna, Austria

Objectives: *Candidatus Mycoplasma haemolamae* (CMHl) infection in llamas and alpacas may either lead to acute diseases with severe anaemia or chronic diseases associated with emaciation or fertility disorders. However, many animals are rather asymptotically infected playing an important role as pathogen reservoir. Reports of CMHl infections of camelids in Europe are rare and only available from the United Kingdom and Switzerland. Therefore it was the aim of this study to assess the prevalence of CMHl in Austrian llamas and alpacas in order to determine potential risk factors associated with CMHl infection.

Materials and Methods: A representative number of llamas and alpacas were investigated nationwide. The animals included in this study were clinically healthy. Regarding the age of the animals, the llamas and alpacas were divided into two groups, whereupon one group included animals between 1 and 2 years of age and one group included all animals older than 2 years. Blood samples were collected from the external jugular vein using K2 EDTA sample tubes. The blood was examined for CMHl using PCR. Prevalence data were assessed and compared to geographical region, age, sex, species, and origin of the animal using the Chi² test.

Results: From a total number of 461 blood samples examined, collected from 193 llamas and 268 alpacas, CMHl was detected in 119 (25.8 %) samples employing species-specific PCR. Furthermore, CMHl was detected significantly more often in alpacas (*Vicugna pacos*) than in llamas (*Lama glama*) with a p-value of 0.001, and more frequently in younger animals (age < 2 years, p = 0.008). Additionally, regional differences in the prevalence of CMHl have been observed, representing a less frequent infection rate in the western parts of Austria. Although not significant, male animals were infected more frequently. Looking at the origin of the animal no statistically significant difference between animals born in Austria and animals imported from foreign countries was evident.

Conclusions: In the present study a high prevalence of CMHl in apparently healthy animals was observed confirming the important role of healthy animals as pathogen reservoir. Results of this study also indicate furthermore different risk levels of infection between llamas and alpacas and between younger and older animals. Regional differences in the prevalence of CMHl may be associated with climatic differences and/or variations in the presence of appropriate insect vectors. However, the data presented in this study underline the necessity of further studies on the significance of CMHl in llamas and alpacas.

The effect of breeding season on the gestation length of alpacas in the UK

Karin Mueller^{1,*} James M. McLeod²

¹School of Veterinary Science, University of Liverpool, Liverpool, United Kingdom, ²Collaroy Veterinary Services, Collaroy, Australia

Objectives: The long gestation period of the alpaca (*Vicugna pacos*) makes continually achieving one offspring per year difficult. There is considerable variation around the average of 345 days. The reasons for this, and possible opportunities to influence it, are poorly understood.

Outside their native South America, alpacas are non-seasonal breeders. In the UK, most breeders choose to mate between Easter and early autumn. In horses, gestation length differs depending on breeding season. Similar findings were reported for alpacas in New Zealand. This study aimed to establish whether this phenomenon could be observed in the Northern Hemisphere.

Materials and Methods: Reproductive data spanning one to eight years was collected from five alpaca farms in the South East of the United Kingdom (latitude 51°32'N). Most animals were of the Huacaya type. All farms had a similar breeding regime, using pen mating at weekly intervals until the dam became non-receptive. Mating dates and parturition dates were obtained. Data from two farms also allowed calculation of birthing rate (defined as number of dams producing a live cria out of all dams mated). Pregnancy was assumed to have resulted from the last recorded mating for each dam.

Matings before or on the 21st June of each year were classed as 'spring', and those after 21st June as 'autumn'. The summer solstice was chosen based on extrapolation from seasonal-breeding species that are influenced by daylight length.

Unpaired T-tests were used for statistical analysis of gestation lengths, assuming equal variances. Fisher exact test was used for birthing rates.

Results: The gestation length for 736 dams was available. Average gestation length was 345.4 days (SD 13.0 days). Spring matings resulted in a gestation length that was 10.9 days longer than autumn matings (p<0.0001). This pattern was found for all farms in the study. From May to September, for every day mating occurred later gestation length decreased by 0.1 or 0.3 days, respectively, depending on the type of trend line fitted.

The birthing rate was significantly lower in autumn (74.0%) compared to spring (82.7%; n=639; p<0.02), and more matings were performed per dam in autumn.

Conclusions: Breeding season does affect the gestation length of alpacas in the UK, and autumn matings would appear to be beneficial to increase reproduction rates. However, the lower birthing rate and higher number of matings in autumn may negate this advantage.

Similarly, there may be a difference in survival and growth rates of crias born in either spring or autumn. Studies on these and other aspects are required before advice can be given on the optimal mating season to maximise reproductive performance in UK alpaca herds.

Further studies are required to elucidate what causes the difference in gestation length.

Blood serum steroid, thyroid hormone, and insulin concentrations in healthy male and female alpacas

Kellie Fecteau^{1,*} Luca Giori¹ Hugo Eiler¹ Andrea Lear² Ricardo Videla²

¹Biomedical & Diagnostic Sciences, ²Large Animal Clinical Sciences, The University of Tennessee, Knoxville, United States

Objectives: Although native to South America, alpacas have gained popularity in several countries including the United States. With this increase in popularity comes the need for veterinary care including the determination of species specific reference intervals to aid in evaluating health status. Therefore, the objective of this study was to determine the concentration of adrenal and gonadal steroids, thyroid hormones, and insulin in male and female alpacas.

Materials and Methods: Physically healthy male and female Huacaya and Suri alpacas from privately owned farms in Tennessee were used in this study. Blood samples were collected from the jugular vein of 37 males (35 intact, 2 castrated; age 1-15 years) and 53 intact females (age 2-12 years) from August to October, 2015. Blood serum was stored at -80°C until analyzed for cortisol, progesterone, 17-hydroxyprogesterone, estradiol, androstenedione, testosterone, thyroxine (T4), triiodothyronine (T3), and insulin at The University of Tennessee Clinical Endocrinology Service.

Results: Hormone results (min-max) for male and female alpacas, respectively, were <1.0-2.9 µg/dL and <1.0-1.5 µg/dL (cortisol); <0.20-0.36 ng/ml and <0.20-5.36 ng/ml (progesterone); 0.06-1.04 ng/ml and 0.02-0.24 ng/ml (17-hydroxyprogesterone), <10.0-36.8 pg/ml and <10.0-44.7 pg/ml (estradiol); 0.03-2.05 ng/ml and 0.04-0.93 ng/ml (androstenedione); 19.4-403.0 ng/dL and <15.0 ng/dL (testosterone); 4.2-11.8 µg/dL and 3.9-10.3 µg/dL (T4); 48.7-403.0 ng/dL and 72.4-380.0 ng/dL (T3). Insulin concentration was <2.0 µIU/ml for all alpacas in the study except for 1 male (4.4 µIU/ml) and 1 female (2.5 µIU/ml), and testosterone concentration in the castrated males was <15.0 ng/dL. For cortisol, progesterone, estradiol, and testosterone, several animals were below (as indicated by the < symbol) the lowest standard of each hormone assay. Approximately 80% of female alpacas in this study have progesterone <0.20 ng/ml. At this time, it is not known if the female alpacas with progesterone above <0.20 ng/ml are pregnant or if these values reflect luteal activity without pregnancy.

Conclusions: The hormone concentrations determined in this study provide an initial endocrine database for male and female alpacas. This information aids in physiological characterization of alpacas and can be used by veterinarians in the clinical evaluation of suspected endocrine dysfunction.

Successful protocol of caesarian section in Arabian camels (*Camelus dromedaries*) in the Emirate of Abu Dhabi, UAE

Abdulwahhab A. Al-Juboori^{1,2} on behalf of Baker M, Tabbaa M J and Al Wahedi AMaher M. Baker²Mohammad J. Tabbaa¹Ameen N. Al Wahedi¹

¹Development and research, ²Animal Health, Abu Dhabi Food Control Authority, Abu Dhabi, United Arab Emirates

Objectives: Seventy eight caesarean operations from different breeds of camels were performed during the period between October 2013 and April 2015, Abu Dhabi Emirate. All cases were diagnosed as dystocia and were unsuccessfully managed by mutations or fetotomy. The causes of dystocia were recorded. The present study was designed to describe successful protocol of caesarian section in camels under field condition in the Emirate of Abu Dhabi, with references to indications, preoperative preparation, operative site, anesthesia, surgical technique, post operative care, operative and post-operative complications and dam and calf survival.

Materials and Methods: Seventy eight caesarean section operations of different breeds of camels (Sudani, Omani, Hazmi and Crossbred, 10, 44, 11 and 13 animals, respectively) were performed. These caesarean sections were done under field conditions by a veterinary surgeon specialist at Al-Tiba Veterinary Hospital, Abu Dhabi Emirate, during the period between October 2013 and April 2015. All cases in
